Quality Heterogeneity and Misallocation: the Welfare Benefits of Raising your Standards[*]

Abstract

Domestic regulations on product standards are a key point of contention in modern trade agreements, but frameworks generally ignore their heterogeneous impact across domestic firms. Using data from Chile, we find that more restrictive domestic standards are associated with a reallocation of domestic sales from low- to high-quality firms. Guided by this evidence, we study the welfare effects of quality standards in a model with monopolistically competitive, heterogeneous firms, and a general demand system. Raising the quality standard forces low-quality firms to exit. Welfare improves if low-quality firms over-produce in the market allocation relative to the efficient allocation. A reduction in trade costs reduces the optimal restrictiveness of a standard in a cooperative equilibrium across countries. We calibrate our model across Chilean industries and find that in several instances the imposed standard is too restrictive relative to a theoretical upper bound. There is suggestive evidence that a rise in openness has reduced restrictiveness, which supports the efforts to improve agreements on product standards along with traditional trade policy tools.

Keywords: Allocative Efficiency, Minimum Quality Standards, Variable Markups, Trade Policy.

1 Introduction

Regulations on goods' characteristics are an important tool applied by policy makers. For example, standardization of technical requirements for products is a major priority of the European Commission growth initiative[1]. Governments choose to impose standards in the domestic economy for many legitimate reasons, e.g. standards on auto emissions to counter the negative externality imposed on society through pollution, or standards in the food industry to protect consumers from disease. Although these regulations are targeted at protecting domestic constituents, technical standards are hotly debated in the context of international trade (Maskus et al., 2000; Baldwin et al., 2000; Rodrik, 2018)[2]. In fact, domestic regulations are often viewed as a barrier on market access of foreign firms (Baldwin et al., 2000; Chen and Novy, 2011; Fontagné et al., 2015).

However, non-discriminatory regulations affect all firms selling to an economy, regardless of their origin, and are aimed specifically at low-quality firms, which are not able to satisfy the requirements imposed by the government. Regulations therefore generate a reallocation of production from low-quality firms to high-quality firms, the welfare implications of which are ambiguous. In this paper, we show that technical measures can improve welfare in the presence of firm heterogeneity by reducing the distortions that arise in allocatively inefficient markets. Such distortions originate from the interaction between consumers' preferences and firms' variable market power. Furthermore, we study the effects of trade openness on the optimal degree of restrictiveness of standards. From a policy perspective, we therefore provide a new framework to approach regulatory standards in the negotiation of trade agreements.

We motivate our theoretical framework by documenting the effects of regulations on domestic firms. We compare the sales and survival "premium" that high-quality firms receive, relative to low-quality ones, when industries become more restrictive in their technical requirements. The specification controls for industry-year shocks and time-invariant firm specific characteristics, which is possible with a panel data of Chilean firms and the TRAINS database on domestic regulations on product standards. The main result is that the differences in terms of sales and survival premium of high-quality firms, relative to low-quality firms, are magnified in industries with a larger number of regulations. We interpret this as a reallocation of production from low-quality firms towards high-quality firms.

To study the welfare consequences of such a reallocation, we incorporate regulations on

[2] In the international trade context, these regulations are labeled technical measures to trade and consist of sanitary and phythosanitary standards and technical barriers to trade (UNCTAD, 2012). The relevance of technical measures in today's trade agreements has surged partly because of the secular decline in tariffs and in the uses of traditional trade policy tools as quotas.

product standards into a standard framework of perfect information, monopolistic competition, and firms that are heterogeneous in quality. We represent the imposition of regulation as a minimum level of quality that a government allows in the market: a minimum quality standard. However, our results generalize to all vertical norms that require the payment of a fixed cost of compliance[3], and do not discriminate between domestic and foreign firms. Consistent with the evidence, raising the standard or, equivalently, making regulations more stringent, forces low-quality firms to exit and, thus, it reallocates production from low-quality to high-quality firms.

There are two opposing effects on welfare. First, the quality standard reduces the total number of varieties available for consumption, as the low-quality varieties exit. In models featuring love for variety (Krugman, 1980), as ours, fewer varieties reduce welfare in conjunction with a weaker competitive environment. Second, the standard improves the average quality in a market, as production moves from low-quality to high-quality firms. The latter channel works to improve welfare when there are distortions in the initial allocation.

To provide a general framework to analyze allocative inefficiency, we choose the "Generalized Translated Power" (GTP) preferences proposed by Bertoletti and Etro (2018), which include some of the most common preferences used in the trade literature: indirectly additive (IA), directly additive (DA), and homothetic[4]. Given the generality of the demand system, it is striking that the model predicts a non-monotone, hump-shaped relationship between the quality standard and welfare for all parametric specifications. At low levels of the quality standard, improving allocative efficiency dominates the welfare loss from diminishing variety and competition. Eventually the standard becomes too restrictive — above its optimal level — when the welfare loss from diminishing the number of firms offsets the welfare enhancing components of the standard.

We clarify the mechanisms through which the standard reduces distortions by comparing the market allocation to the socially optimal allocation. Generally, there are three margins through which the market is inefficient: the selection of firms, the quantity produced by each firm, and the number of firms that attempt to enter the market. We limit the analysis to the allocation of production among entrants (the first two margins) by making an assumption common to the literature with firm heterogeneity, that firms draw their quality from a Pareto distribution (Chaney, 2008; Arkolakis et al., 2012, 2017).

---

[3] We focus on vertical norms, which are easily characterized as being more or less stringent, such as limits on car emissions or on residue levels of pesticides. We abstract from costs associated with the enforcement of the standard that are paid by the government. Moreover, we ignore horizontal norms, which arise when the local firms' differentiated good is adopted as a norm, as electric plugs (Baldwin et al., 2000).

[4] We derive our main theoretical results for a closed economy to abstract from protectionist motives that arise when governments use trade policy to internalize some form of market power (Alvarez and Lucas, 2007).

The distortion reduced by a quality standard is known as "business stealing bias", where too many low-quality firms are active in a market, relative to an optimal allocation[5]. In addition, due to the markup distribution, high-quality firms under-produce and low-quality firms over-produce, relative to an efficient allocation. A necessary condition for such a misallocation is that firms charge variable markups – consumers are willing to purchase low-quality goods provided that those markups are low enough in the laissez faire economy. The standard causes a reallocation of production from low- to high-quality firms, which we label the *composition effect* of the standard.

The composition effect achieves a rise in welfare by reducing distortions through an increase in the weighted average markup due to the reallocation. However, as the standard reduces the number of competitors, it can generate *anti-competitive* effects, whereby welfare is reduced as surviving high-quality firms increase their markups in response to lower competition. The optimal degree of regulations depends on the elasticity of a firm's markup with respect to the number of competitors. The three preferences included in GTP differ in the extent of anti-competitive effects, which are absent in the IA case and are the largest under homothetic preferences. Hence, the model predicts the most restrictive optimal standard under IA, intermediate under DA, and the smallest under homothetic preferences.

A further contribution of the paper is to study the effects of trade openness on the optimal degree of restrictiveness of standards. We abstract from a political economy problem (Bagwell and Staiger, 2001) and consider the optimal standard chosen by two symmetric countries in a cooperative equilibrium. Such a scenario could represent the negotiating phase in trade agreements. The model predicts that trade openness and quality standards are complements: lower trade costs reduce the optimal level of the quality standard. The intuitive mechanism is that trade reallocates production from low-quality non-exporters to high-quality exporters, in a sense doing the work of the standard, and thus reducing its welfare improving ability[6]. Although there is always a low enough quality standard that is welfare improving, as economies open to trade the optimal level decreases. For this reason, this paper offer support of a dual approach for policymakers: pushing towards lower trade costs while lowering unnecessary restrictiveness of quality standards. The result provides a

---

[5]This intuition is present in Mankiw and Whinston (1986) and Dhingra and Morrow (2016). The business stealing bias dominates another distortion commonly labeled "lack of appropriability", which generates *too little* production from low-quality firms, and occurs when firms cannot fully seize or appropriate the gains from a new variety. Quantitative evidence for this type of misallocation has been highlighted in the aggregate productivity literature (Basu and Fernald, 2002; Restuccia and Rogerson, 2008; Hsieh and Klenow, 2009) and in the trade literature (Edmond et al., 2015; Weinberger, 2017).

[6]The result arises *even* keeping the selection of domestic firms constant, as with IA preferences. We focus only on the quality standard, so that the optimal tariff results of Felbermayr et al. (2013) and Demidova and Rodriguez-Clare (2009) are beyond the scope of this paper.

theoretical justification for the continuous efforts from the WTO of improving the Technical Barriers to Trade Agreement, which has now reached the Eighth Triennial Review[7].

To quantify the effects of technical measures, we estimate our model across 40 Chilean manufacturing industries[8]. We note that, although a quality standard allows for an intuitive theoretical mechanism through which low-quality firms exit, in reality there can be numerous policies that generate the same distributional effect on production. We estimate the consequences of all such measures imposed in the industry and find a significant presence of measures across Chilean industries. For example, in 2000, the presence of technical measures reduced the survival probability of a firm by 40% on average. The restrictiveness of technical measures is also heterogeneous across industries: Chemicals, Motor Vehicles, Food, and Books/Journals are consistently the most regulated industries, while Furniture and Apparel are the least regulated, with a reduction in the survival probability of a firm close to 10%.

We then conduct a policy-relevant evaluation by comparing the estimated level of restrictiveness with a theoretical upper bound for the restrictiveness of the standard predicted by our model[9]. In 5 out of 38 industries in 2005, we cannot reject the hypothesis that the estimated standard is different than the theoretical upper bound. Hence, in those five industries, the standards are too restrictive in light of our model. Moreover, the number of industries that are too restrictive has declined since 2000. We postulate that an increase in openness could be a factor in reducing the restrictiveness of technical measures, as Chile experiences a boom in trade after 2000. This is exemplified not only by the observed increase in trade flows, but the passage of important free trade agreements with the United States, EU, and China. There is suggestive evidence that the reduction in restrictiveness is largest in the most open industries. This finding reinforces the paper's support for a dual approach of reasonable standards along with lower trade costs.

Relationship with the Literature. Our paper relates to a growing literature within the trade, industrial organization, and macro fields, on the aggregate consequences of misallocation of production across heterogeneous firms. The presence of misallocation provides a unique channel through which reallocation impacts welfare (Basu and Fernald, 2002; Hsieh and Klenow, 2009; Dhingra and Morrow, 2016). However, practical policy implications are rarely provided as a way to improve upon the observed allocative inefficiency[10]. In this paper we explore the case where a policy-maker can set a minimum level of quality that is

---

[8]Our estimates of the implied survival restrictions in Chilean industries is similar to Behrens et al. (2018) who use firm revenues/employment to estimate the distortions present within French industries.

[9]This upper bound is the optimal standard in a closed economy with IA preferences. In fact, trade reduces the need for regulations and IA preferences generate the largest restrictiveness of the optimal standard.

[10]Direct policy implications of misallocation include a tax on entry and complicated schemes of firm taxes/subsidies to get the optimal distribution of sales.

allowed to sell in a market, and generalize the result to the payment of a fixed cost that achieves the same allocation. We show that under a plausible set of conditions – governed by the demand faced by firms – regulatory measures imposed on goods' characteristic can raise welfare through an increase in allocative efficiency. The extension of optimality results in Dhingra and Morrow (2016) and Bertoletti and Etro (2018) to a framework with quality differentiation, is a separate contribution of this paper.

An important contribution is to provide a rationale for technical standards that has not been explored in any of the previous literature. Quality standards could be raised to address negative externalities, such as environmental externalities (Parenti, 2016; Mei, 2017), to reduce oligopolists' market power (Baldwin et al., 2000), or to enhance investments in quality upgrading (Gaigne and Larue, 2016). Other reasons, yet to be explored in the context of international trade are information asymmetries or, more generally, information frictions (Schwartz and Wilde, 1985). Last but not least, technical measures could be used as murky protectionism (Baldwin and Evenett, 2009), as studied by Fischer and Serra (2000) in the context of an international duopoly. This paper acts as a complement to the existing literature on rationales for regulations as it is the first explore the role of inefficient markets. Since our quality standard generalizes to all vertical norms, it potentially allows for more general policy responses.

The trade literature has traditionally considered regulations on product standards as a form of barriers to trade that primarily impacts the extensive margin of firms. In this vein, studies have relied on export flows to show that exporters, and in particular the smallest ones, from a specific origin (e.g France) are less likely to sell a product to destinations that impose relatively more regulations in those products (Fontagné et al., 2015; Fernandes et al., 2015; Ferro et al., 2015). We separate from this literature and examine the effect on domestic firms instead, with a focus on the distribution of firm sales[11]. Our approach fits with the emphasis on firm selection and reallocation of production that are integral to gains from trade when firms are heterogeneous and compete monopolistically (Melitz, 2003).

This paper is organized as follows. Section 2 presents the stylized facts that motivate our modeling choice. Section 3 describes a framework with generalized translated power preferences and quality differentiation, where a policy maker may impose a quality standard. Section 4 shows the results from estimating the model. Section 5 concludes.

---

[11]The technical measures we examine are imposed on all firms in the economy, not necessarily intended as a trade restriction.

2   Motivational Evidence

The theory in Section 3 frames regulations on product characteristics as a quality standard. Firms with quality below the standard exit, so that their production is reallocated to the rest of the firms in the industry. The measure of active firms, their average quality, and the distribution of sales across these firms determine the level of consumer welfare. In this section, we aim to motivate this intuitive approach with firm-level data that allows us to observe survival and sales distributions at the finest industry disaggregation available (4-digit ISIC). We take a balanced panel of Chilean firms and provide evidence of a relationship between the imposition of regulations at the industry level and a growing differential of survival and sales across low- and high-quality firms. In industries with a higher level of quality standards, there is indeed stronger selection of high-quality firms, and the sales distribution is skewed more heavily towards the high-quality firms.

2.1   Data

Detailed Database of Non-Tariff Measures.   In order to map our regulations to the data, we make use of the prevalence of technical measures. Technical measures are *domestic* regulations that the WTO interprets as limiting market access. With the secular decline in import tariffs, trade economists have pointed towards technical measures as an increasingly relevant subject in trade agreements (Maskus et al., 2000; Baldwin et al., 2000). Specifically, sanitary and phytosanitary (SPS) and technical barriers to trade (TBT) are now the most crucial technical policies (UNCTAD, 2017).

TRAINS has recently been made available a comprehensive database of technical measures imposed by WTO members[12]. The database includes *all* domestic regulations found in official texts that can be classified as an non-tariff measures (NTMs)[13]. The 2012 NTM classification separates measures into 16 chapters (labeled A-P), and we make use of the first two chapters: SPS and TBT, to construct our measure of quality regulation. These two chapters are defined by UNCTAD (2017) as "technical measures," and therefore fit most closely with our quality standard in the theory. These are the regulations that Ferro et al. (2015) and Fontagné et al. (2015) have shown to primarily reduce the extensive margin of exporters. We emphasize that these are regulations imposed in the domestic market, so that an important advantage of this data is that the technical regulations apply to both imported

---

[12]The web application to retrieve the data is available at http://i-tip.unctad.org/.

[13]TRAINS collects official measures imposed by countries that might affect international trade, that are mandatory, and are currently applied. National governments or local consultants hired by the World Bank collect regulations from official government sources, such as Customs Agencies or Government Ministries.

products and locally-produced goods. They therefore represent technical measures that do not discriminate between domestic and foreign firms[14].

From the reporter (imposing country)-product-NTM code-year data, we construct a measure of industry restrictiveness that can be merged to our domestic production data. First, we allow each product to have at most one regulation imposed per NTM (2 digit) chapter in each year, and aggregate the number of regulations for each 4-digit ISIC (revision 3) industry. To control for the number of products in each industry, we divide the previous sum by the number of HS6 products in the 4-digit industry[15]. Finally, the industry classification allows us to merge the measures to the firm data which we describe next. Table 2 in appendix 6.1 lists the top 25 industries ranked by the restrictiveness in the 1995-2007 period. Unsurprisingly, these rankings are populated by food and pesticide products due to the presence of SPS regulations, along with chemicals and equipment machinery.

Chilean Firm Data. The Chilean data is a census that provides a panel of firms with more than 10 employees from 1995-2007, provided by Encuesta Nacional Industrial Anual (ENIA, National Industrial Survey) and collected by the National Institute of Statistics (INE). Each firm is classified with a 4-digit ISIC industry. There are approximately 5,000 firm level observations per year and firms are tracked across time with a unique identification number. Each firm provides detailed economic data such as total sales, value/usage of its factors, etc.

The key limitation, as faced by previous literature, is that there is no explicit measure of quality. We rely on input measures to construct a proxy for quality: we take the firms' capital stock, labor costs, and intermediate input costs, and divide each by the number of employees. Higher capital intensity, average wage per worker, and average material input costs all arguably correlate with quality, and have been used in previous studies (Kugler and Verhoogen, 2012; Hallak and Sivadasan, 2013)[16]. Hallak and Sivadasan (2013) use the same quality proxies for Chile, however they complement these with Indian product-level data that allows them to also use the adoption of ISO 9000 certification and input/output prices.

---

[14]In contrast, the Specific Trade Concerns data used in Fontagné et al. (2015) lists concerns raised by trading partners. To safeguard against discriminatory technical measures, in the main specification we drop "Pre-shipment Inspections" (Chapter C in the NTM classification, which is often represented as a technical measure), as well as classifications A1 and B1 within the SPS and TBT chapters respectively, as these are most likely to include regulations that only affect imported goods. Results that include these chapters do not alter our conclusions.

[15]Re-defining the TM measure without controlling for the number of HS6 products does not change the results

[16]The three proxies are positively correlated with a ratio of skilled workers to unskilled workers, using a (rough) measure in the Chilean data that labels a category of workers as unskilled (or "no calificados" in Spanish). Not surprisingly, the correlation is strongest with the wages per worker quality proxy.

7

When they investigate the exporter quality premium conditional on size, they find very similar results across all of the quality proxies. Therefore, the three proxies in our paper are likely capturing very similar attributes as the more direct quality measures, although access to product price data would allow us for better proxies of quality. In order to create a quality indicator, we label a firm as "high-quality" if it is above the median in the quality proxy within its industry in 1995.

2.2 Technical Measures and Chilean Firms

The data described above allows us to test the distributional effects of technical measures within industries. To do so, we run the following specification:

$$y_{fit} = \alpha_{it} + \alpha_f + \beta_M TM_{it} * Quality_f + \beta_X X_{it} * Quality_f + \epsilon_{fit}, \tag{1}$$

where y_{fit} is a performance measure for firm f in industry i at year t which includes log domestic sales and a dummy for positive sales ("survival premium"). TM_{it} is the measure of industry restrictiveness based on the imposition of SPS and TBT measures as reported in Table 2. The main coefficient of interest is β_M, which identifies the high- versus low-quality differential response to the imposition of regulations in an industry-year.

We include industry-year (α_{it}) and firm (α_f) fixed effects to control for the variety of industry and macroeconomic shocks, plus time invariant firm characteristics. This restrictive specification only captures the relative firm outcomes that are due to changes in technical measures and not due to the various industry characteristics that might drive the firm sales distribution[17]. The time-varying controls, $X_{it} * Quality_f$, capture changes in non-regulatory industry characteristics that might drive relative outcomes between high- and low-quality firms. These include an interaction of industry openness with the quality indicator to make sure we are not capturing differences in competition introduced by trade, and an interaction of the quality indicator measure with the level of import tariffs at the industry level[18].

In our main specification, we consider a balanced panel of firms. We keep only firms alive in 1995 and construct a balanced panel where a firm is given a survival dummy equal to 0 if it does not sell in that year. This follows the specification in Fontagné et al. (2015) and allows us to interpret the firms in the first year as the "potential" producers. Firms are assigned a quality indicator based on being above or below the median in 1995[19]. To some

---

[17]Our specification controls for time-varying industry characteristics, as well as time-invariant firm characteristics, that are correlated with the sales distribution. For example, differences in product differentiation and demand elasticities across firms and industries are controlled for with the fixed effects.

[18]As described below, import tariffs declined in this period, although mostly uniformly across industries.

[19]For the specification with sales as an outcome, our results are robust to using the unbalanced panel.

degree the results on the "survival" outcome are affected by the fact that firms with less than 10 employees are not forced to participate to the survey. However, given that we find exit to be more prevalent among the smallest firms and the sign on relative survival (β_M) is in the direction that we expect, the censoring of the data likely *understates* the magnitude of the firm churning.

Results. Table 1 reports the main motivational results. We include the controls detailed above but only report the main coefficients of interest β_M. The results on domestic sales suggest that the ratio of sales between high- and low-quality firms is magnified when industries become more regulated. The coefficient in the first row of column (1) implies that a 10 percentage point increase in the coverage ratio of technical measures result in a .15% larger sales difference between an average high-quality firm relative to the average low-quality firm, with a p-value of 0.01. The three proxies for quality yield similar results, although they are the most precise when using capital intensity. The next table suggests that the survival of high-quality firms relative to low-quality firms is also higher in more regulated industries. In this case, only the capital intensity results are statistically significant below the 5% level, but the sign is positive and of similar magnitude for all proxies of quality.

The results of this section are consistent with the following intuition: in industries with more regulations there is more exit of low-quality firms, and this reallocates production to the high-quality firms. β_M is not interpreted as a causal relationship between the imposition of technical measures and sales/survival heterogeneity, but instead we motivate the model by highlighting the existence of this relationship. These results also line up with the findings in Fontagné et al. (2015) that regulations hurt the small exporters the most, assuming that the small exporters are also viewed as selling lower quality.

In the appendix we show that there is a very strong correlation in the data between all the quality proxies and firm sales, which allows us to interpret a quality standard as essentially eliminating firms in the left tail of the sales distribution. Furthermore, we also show that there is a very strong relationship between all the quality proxies and a measure of TFP. This result is important because our theoretical results with quality heterogeneity can be translated to productivity heterogeneity but only in the familiar case that quality is proportional to productivity. In summary, our empirical findings motivate the framework of the rest of the paper, with firms differentiated by quality and a standard which eliminates the lowest quality firms. As the market equilibrium is not necessarily efficient, the reallocation set off by the technical measures can be welfare improving.

As there are several caveats to keep in mind, in Section 4, in order to not rely on the possibly flawed data on technical measures, we estimate industry restrictiveness from the

Table 1: Firm Sales (top) and Survival (bottom) Heterogeneity - by TMs in Industry

	Log Domestic Sales		
	(1)	(2)	(3)

Results from OLS estimation of (1). Robust std. error in parenthesis. Cluster: industry. ***: significant at 99%, ** at 95%, * at 90%. TM_{it} (restrictiveness) is measured at the 4 digit ISIC industry level. The total number of measures in each industry-year are summed and then divided by the number of HS6 products in the industry. Each row interacts the TM measure with a dummy for quality, where quality is proxied by capital per worker, total wages per worker, and input expenditure per worker respectively. Firms are high-quality if the quality proxy is above the median in that industry in 1995. For the results on survival, all firms alive in 1995 are "potential" producers in all years, which is why the number of observations is much larger. In all specifications we include an interaction of industry openness with the quality indicator, an interaction of the quality indicator measure with the industry import tariff, plus firm and industry-year interacted fixed effects.

structure of the model by backing out the implied restrictiveness given the empirical sales distribution. Next, we briefly describe several robustness results to the above empirical specification that are reported in Appendix 6.1.

Robustness. A common issue with data on regulations is the high level of measurement error. For instance, there could be a mismatch between the date of initial enforcement of a regulation, and the date of its listing in the dataset. To address the concern, we run a specification where regulations are aggregated across all years so that there is *one* restrictiveness measure for each industry. In this case, the specification is a repeated cross-

section, with sales as the outcome within industry-year, and ran on an unbalanced panel[20]. We find that more regulated industries exhibit higher skewness in sales towards high-quality firms, which suggests that the timing of when regulations are listed does not drive the results.

An implicit assumption that we make is that technical measures are non-discriminatory. In fact, regulations must fit this criteria to be legal under WTO rules, and we attempt to omit technical measures that might be more heavily weighted towards importers. To test this assumption, we create our TM variable using only a subset of technical measures dropped from the main analysis that might be aimed at importers – those classified by UNCTAD as "Prohibitions/restrictions of imports for SPS reasons" and "Prohibitions/restrictions of imports for objectives set out in the TBT agreement". Since these are the measures least likely to affect domestic firms, we expect to not find the same type of evidence for reallocation. In fact, we find the opposite result of our baseline specification: in 5 of the 6 interactions the coefficients are negative. We caution however that these results have large standard errors as there are few technical measures that fit this definition[21].

Our dataset contains both vertical and horizontal norms, altough our theoretical framework only considers vertical norms. As a way deal with this issue, we replace the set of technical measures used in specification (1) with more specific subset of technical measures (Table 6 in the Appendix). For example, we construct two versions of TM using SPS and TBT separately. Either type of technical measure is associated with a widening of sales dispersion and lower survival for low-quality firms. However, the results are stronger in the case of SPS regulations – mostly due to much smaller standard errors. This could be due to the fact that SPS measures are more prevalent than TBT ones, which we find to be the case. However, this suggests the results are likely not driven by horizontal norms, which are arguably more likely to come in technical regulations under TBT[22].

Finally, we include an IV specification in the appendix where TM is instrumented using the TM measure in *Peru* interacted with the same quality indicator. This specification minimizes the concern that Chilean regulations may reflect Chilean consumers preference for quality[23]. Although the results are weaker, the qualitative story stays the same.

---

[20]The main drawback in this case is we cannot control for firm fixed effects. Since the regulations are aggregated from the HS 6 product level, firms within the same 4-digit ISIC might actually be exposed to different levels of regulation. We add an interaction with industry trade elasticities (from Broda and Weinstein (2006)) to control for the effect of demand characteristics on the sales distribution – which was controlled for in the previous specification by firm fixed effects.

[21]One coefficient is positive and large (though insignificant), but overall the results do not point to the same reallocation effects present with the other measures.

[22]The presence of measures based on horizontal norms likely biases our results towards zero. These measures do not discriminate on any attributes related to quality, which means that "treated" industries will receive no distributional impact.

[23]We use the TM in Peru because we find this country to be closest to Chile in terms of regulatory structure

3 Theory

This section builds a theory for the welfare effects of technical measures, in the form of minimum quality standards. We begin by presenting the description of the environment, with a standard supply side and a general demand system that nests both non-homothetic and homothetic preferences. Then, we proceed by allowing a policy maker the option of imposing a quality standard, whose effects on the distribution of firms are consistent with the evidence documented in the previous section. A standard more restrictive than the market allocation is always optimal. We derive an expression for welfare as a function of the standard, which depends on several parameters. First, regardless on the type of preference, the optimal standard increases as the dispersion in quality and the demand curvature increase. Second, given demand and supply parameters, the optimal standard depends on the relationship between firms' demand elasticities and the level of competition. Namely, as firms' markups are more sensitive to the level of competition, the standard becomes less beneficial. However, *reallocating* production to firms with higher markups is welfare improving up until the loss of competition is large enough. We discuss the sources of market distortions that a minimum quality standard reduces, and identify the features of each type of preferences that cause shifts in the magnitude of the optimal standard in an economy. Given the generality of this demand system, our welfare results provide a strong motivation for the rationale of a quality standard. We end the section with a study of the effects of trade openness on the optimal quality standard that two countries cooperatively choose.

3.1 Framework

Consider a closed economy, where L consumers enjoy the consumption of varieties of a differentiated good. We normalize per capita income to 1. The varieties are produced by a mass of single-product firms, which differ in terms of their quality z. We assume that quality z is a demand shifter: consumers exhibit a higher willingness to pay for higher quality goods. There is perfect information: consumers, firms, and the government are able to costlessly distinguish between the quality offered in the market.[24]

As in the Melitz (2003) model, there is a pool of potential entrants. Upon entry, firms pay a fixed cost of entry f_E in labor units and discover their quality z. Quality is drawn from an unbounded Pareto distribution with shape parameter κ and shift parameter b. The

---

across industries (and therefore the F-stat in the first stage is very large).

[24]Papers on technical measures often introduce an *ad hoc* externality, usually pollution or public health, to justify the imposition of a standard (Parenti, 2016; Mei, 2017). In this spirit, we can also think of our quality measure as a proxy for how healthy a product is. Despite consumers knowing and appreciating the healthiness of a good, our model features a market allocation that might have too many unhealthy products.

CDF of the distribution is $G(z) = 1 - \left(\frac{b}{z}\right)^{\kappa}$, while the pdf is $g(z) = \frac{\kappa b^{\kappa}}{z^{\kappa+1}}$. Only a mass J of firms pays the fixed cost of entry. Free entry drives expected profits equal to f_E.

The market is monopolistically competitive. All firms produce their goods with the same marginal cost of production c, in labor units. These assumptions imply that size heterogeneity is linked to the exogenous quality draws. The direct mapping of quality to size might seem stark, but it is a convenient feature that is also present in Kugler and Verhoogen (2012) and finds quantitative support in the empirical findings of Hottman et al. (2016).

3.2 Consumer and Firm Problems

3.2.1 Consumer's Problem

We adopt the Generalized Translated Power (GTP) preferences proposed by Bertoletti and Etro (2018):

$$U = \int_{\Omega} \left(az(\omega)\xi q(\omega)) - \frac{(\xi q(\omega))^{1+\frac{1}{\gamma}}}{1 + \frac{1}{\gamma}} \right) d\omega + \frac{\xi^{-\eta} - 1}{\eta} \tag{2}$$

where $a > 0$ and $\gamma \geq 0$ are constants, $q(\omega)$ is the quantity consumed of variety ω, $z(\omega)$ is a variety specific demand shifter, which we interpret as quality, and Ω is the set of varieties available for consumption. ξ is a quantity aggregator that is implicitly defined as:

$$\xi^{-\eta} = \int \left(az(\omega)\xi q(\omega) - (\xi q(\omega))^{1+\frac{1}{\gamma}} \right) d\omega \tag{3}$$

The GTP preferences follow the generalized Gorman-Pollak demand system,[25] which nests several types of preferences based on the value of the parameter $\eta \in [-1, \infty]$. For $\eta = -1$ preferences are indirectly additive (IA) as described by (Bertoletti et al., 2017). For $\eta = 0$, the demand system becomes a special case of homothetic preferences with a single aggregator. For $\eta \to \infty$, preferences become directly additive (DA), and generalize the preferences used by Melitz and Ottaviano (2008).[26] Fally (2018) describes the regularity conditions for these preferences.

The consumer's budget constraint is:

$$\int_{\Omega} p(\omega)q(\omega)dz \leq 1$$

where $p(\omega)$ is the price of variety ω and per capita income is normalized to 1. The consumer chooses $q(\omega)$, $\omega \in \Omega$, to maximize its utility subject to the budget constraint.

---

[25]Gorman (1972), Pollack (1972).

[26]The case where $\gamma = 1$ generates linear demand as in the separable case of Melitz and Ottaviano (2008).

Solving the consumer's problem and aggregating across consumers yield the following aggregate inverse demand:

$$p(\omega) = \xi^{1+\eta} \left[az(\omega) - (\xi q(\omega))^{\frac{1}{\gamma}} \right] \tag{4}$$

3.2.2 Firms' Problem

Given the quality draw z, a firm maximizes its profits by choosing quantity $q(z)$ taking ξ as given. Profits are given by:

$$\pi(z) = L\xi^{1+\eta} \left[azq(z) - \xi^{\frac{1}{\gamma}}(q(z))^{1+\frac{1}{\gamma}} \right] - Lcq(\omega) \tag{5}$$

Profit maximization yields the following optimal quantity, and setting $q(z^*) = 0$ yields the market determined quality cutoff:

$$z^* = \frac{c}{a}\xi^{-(1+\eta)} \tag{6}$$

For a quality level below the cutoff $z < z^*$, a firm has zero demand. The relationship between the cutoff and η will be key in comparing our results across the types of preferences because the demand faced by each firm is governed by the firms' quality relative to the market cutoff. If $\eta = -1$, the quality cutoff only depends on income (normalized to one) $z_{\text{IA}}^* = \frac{c}{a}$, as in the IA case. If $\eta = 0$, the cutoff for homothetic preferences is $z_{\text{H}}^* = \frac{c}{a}\xi^{-1}$, and the cutoff depends only on the number of competitors and is independent of income. Given the relationship between ξ and the marginal utility of income,[27] for $\eta \to \infty$, $z_{\text{DA}}^* = \frac{\lambda c}{a}$. In the DA case, the market determined cutoff depends on *both* income and the number of competitors.

Substituting the market cutoff (6) into the firm's first order condition yields the optimal quantity:

$$q(z) = \left(\frac{a\gamma}{1+\gamma} \right)^\gamma \frac{(z^*)^\gamma}{\xi} \left(\frac{z}{z^*} - 1 \right)^\gamma \tag{7}$$

As $q(z)$ is increasing in z, active firms with higher quality sell larger quantities of their products. Substituting (7) into (4) yields the optimal pricing rule:

$$p(z) = c \underbrace{\frac{1}{1+\gamma} \left(\frac{z}{z^*} + \gamma \right)}_{\text{Markup}} \tag{8}$$

Markups are increasing in z: higher quality firms charge higher markups (Bertoletti and Etro, 2017). Such prediction receives empirical support from Bastos and Silva (2010), Manova and Zhang (2017), Martin (2012) and Dingel (2015).

---

[27] $\lambda = \frac{1}{y} \int \left(az\xi q(\omega) - (\xi q(\omega))^{1+\frac{1}{\gamma}} \right) d\omega = \frac{\xi^{-\eta}}{y}$, where λ is the multiplier on the resource constraint.

Firm z profits and revenues are given by:

$$r(z) = \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma} \right)^{\gamma} \frac{(z^*)^{\gamma}}{\xi} \left(\frac{z}{z^*} - 1 \right)^{\gamma} \left(\frac{z}{z^*} + \gamma \right) \tag{9}$$

$$\pi(z) = \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma} \right)^{\gamma} \frac{(z^*)^{\gamma}}{\xi} \left(\frac{z}{z^*} - 1 \right)^{1+\gamma} \tag{10}$$

3.3   Quality Standard and Welfare

The government of the closed economy sets a minimum quality requirement $\bar{z} \geq z^*$, such that a firm with quality $z < \bar{z}$ is not allowed to sell in the economy. The quality requirement is a vertical norm (Baldwin et al., 2000): $\bar{z}$ can be easily interpreted as more or less restrictive. Since firms' quality is exogenously determined, the policy only affects the selection of firms into the domestic market (Figure 1). In particular, the larger $\bar{z}$ becomes, the more low-quality firms are forced out of the market. The model is consistent with the evidence documented in section 2.

Our results generalize to all vertical norms that require the payment of a fixed cost of compliance that must be paid by all firms. We choose to model directly the standard because, in section 4, we will be able to estimate its restrictiveness regardless of the level of the fixed cost. Our model abstracts from any costs associated with enforcing the standard by the government, which would be hard to quantify, and would reduce the welfare benefits of standards. Appendix 6.2.5 investigates the case where the standard is imposed as a fixed cost, which reallocates resources from production to compliance to the regulation. The fixed cost merely generates a downward shift in the level of the optimal standard, but is an important generalization because it allows for a separate way to impose the standard: a policy-maker can impose a fixed production cost that generates the same reduction in the probability of survival as $\bar{z}$.

We abstract from firms endogenously choosing their quality à la (Feenstra and Romalis, 2014), which would not generate any additional sources of distortions. Moreover, raising the standard would raise the quality of the smallest surviving firms, which would raise their revenues and thus reduce the sales difference between high-quality and low-quality firms, contrary to the evidence of section 2. Finally, assuming that to produce higher quality goods a firm incurs higher marginal costs, as in Manova and Zhang (2017), only quantitatively affect the results (see Appendix 6.2.6).

15

Figure 1: Minimum Quality Standard and Selection
It is convenient to write our variables as a function of $g = \frac{\bar{z}}{z^*} \in [1, \infty)$, a measure of the restrictiveness of the quality standard. If $g = 1$, the standard is ineffective: the market-determined quality cutoff z^* is equal to the minimum allowed $\bar{z}$. For $g > 1$, the government is enforcing a higher quality standard than the one determined by the market. The measure g is related to the probability of a firm being active under the restriction, relative to the same probability without the restriction: $\frac{P(z \geq \bar{g}|g>1)}{P(z \geq \bar{g}|g=1)} = g^{-\kappa}$.

3.3.1 Market Aggregates

We start with the market aggregates necessary to compute welfare. Details on the derivations used to compute the aggregates are relegated to the appendix. The equilibrium quality cutoff z^* can be represented as a function of the quality standard and parameters:

$$z^* = \left[\frac{L c^{\frac{\eta}{1+\eta}} \gamma^\gamma b^\kappa a^{\gamma + \frac{1}{1+\eta}}}{f_E(1+\gamma)^{1+\gamma}} g^{-\kappa} G_1(g) \right]^{\frac{1}{\kappa - \gamma - \frac{1}{1+\eta}}} \tag{11}$$

where $g^{-\kappa}G_1(g)$ is decreasing in g.[28] The parameter η controls the elasticity of the quality cutoff with respect to market size L and marginal costs c. In particular, the elasticity of the cutoff with respect to size is $\frac{\partial \ln z^*}{\partial \ln L} = \frac{1}{\kappa - \gamma - \frac{1}{1+\eta}}$. An increase in market size induces selection effects, namely it increases the minimum level of quality allowed by the market, if such an elasticity is positive. Such a condition is satisfied for homothetic ($\eta = 0$) and DA preferences ($\eta = \infty$). However, under IA preferences ($\eta = -1$), where the cutoff is only dependent on income, there are no selection effects due to market size.[29]

---

[28]$G_1(g) = \kappa g^{1+\gamma} \left[\frac{F_1(g)}{\kappa - \gamma - 1} - g^{-1} \frac{F_2(g)}{\kappa - \gamma} \right]$. $F_1(g)$ and $F_2(g)$ are two hypergeometric functions given by $F_1(g) = {}_2F_1 \left[\kappa - \gamma - 1, -\gamma; \kappa - \gamma, g^{-1} \right]$ and $F_2(g) = {}_2F_1 \left[\kappa - \gamma, -\gamma; \kappa - \gamma + 1, g^{-1} \right]$. We restrict the parameter space such that $\kappa - \gamma - 1 > 0$.

[29]The elasticity of the market cutoff with respect to marginal costs c, which is analogous to analyzing income effects in the spirit of Bertoletti and Etro (2018), is $\frac{\partial \ln z^*}{\partial \ln c} = \frac{\eta}{(1+\eta)(\kappa-\gamma)-1}$. Such an elasticity equals zero for homothetic preferences ($\eta = 0$, as in Melitz (2003)), equals one for IA preferences ($\eta = -1$), and equals $\frac{1}{\kappa - \gamma} < 1$ for DA preferences.

In the presence of a quality standard, the selection of firms is determined by the government imposed $\bar{z}$, and not by the market cutoff z^*. However, the market cutoff affects the markups of surviving firms (8). The effects of an increase in the restrictiveness of the standard on surviving firms depends on the elasticity of the market cutoff with respect to L. Under IA preferences, in which the elasticity is zero, the standard leaves the markups of surviving firms unchanged. Under DA and homothetic preferences, the standard increases the markups of surviving firms. We call this the *"anti-competitive"* effect of the standard: it operates under homothetic and DA preferences, but is silent under IA preferences. Finally, notice that the increase in markups, or *anti-competitive* effect, is largest under homothetic preferences.[30]

Substituting (11) into (6) yields the aggregator ξ:

$$\xi = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}} g^{-\kappa}G_1(g) \right]^{-\frac{1}{(1+\eta)(\kappa-\gamma)-1}} \tag{12}$$

which equals one under DA preferences, decreases in g under IA preferences, and increases in g under homothetic preferences. The aggregator ξ is a quantity shifter that affects the volumes of production, along with z^*, of all surviving firms. Hence, the quality standard has a partial negative effect on the volumes produced under IA preferences, and a partial positive effect under homothetic preferences.

Finally, the mass of entrants J is independent of η:

$$J = \frac{L}{f_E} \frac{G_1(g)}{G_2(g)} \tag{13}$$

and is increasing in the restrictiveness of the standard. As an increase in g increases the average profits in the economy, more firms enter. However, the total number of active firms in the economy $N = P(z > \bar{z})J$ is declining in the restrictiveness of the standard.

3.3.2 Welfare

We are now ready to express welfare as a function of the quality standard. After integrating over the two terms in (2) (see appendix), the utility becomes:

$$U = \frac{az^*\xi}{c} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta} \right] - \frac{1}{\eta} \tag{14}$$

---

[30]In fact, one can relate this result to Arkolakis et al. (2017), who show that the effect of *trade costs* on the choke price can be ranked across the same types of preferences.

The term $(1 + \gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)}$, which is a component of the average utility, is always increasing in g.[31]. On the other hand, the product of the quality cutoff z^* and the aggregator ξ is declining in g. Using the cutoff condition (6) and the equilibrium value of ξ (12) yields the utility of consumers as a function of g:

$$U = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma g^{-\kappa} G_1(g)}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}\right]^{\frac{\eta}{(1+\eta)(\kappa-\gamma)-1}} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta}\right] - \frac{1}{\eta} \qquad (15)$$

As shown in figure 2, a minimum quality standard can improve welfare across the three preferences nested into GTP. In fact, the relationship between welfare and the standard is hump-shaped. Starting from the market allocation, imposing a quality standard causes a reallocation of production from low-quality firms to high-quality firms, which is welfare improving. However, the quality standard reduces the number of varieties available for consumption, which is welfare reducing under the assumption of love for variety. For "small" levels of restrictiveness the first effect dominates the reduction in the number of varieties. Increasing the standard over its optimal value causes the variety reduction to dominate, and welfare starts falling.

Figure 2: Minimum Quality Standard and Welfare
The optimal level of the measure of the restrictiveness of the standard $g^{opt}(\kappa, \gamma, \eta)$ only depends on the parameters κ, γ, and η. The optimal level of the standard $\bar{z}^{opt}$ is then

---

[31]$G_2(g) = \kappa g^{1+\gamma}\left[\frac{F_1(g)}{\kappa-\gamma-1} + \gamma g^{-1}\frac{F_2(g)}{\kappa-\gamma}\right]$ and $G_3(g) = \kappa g^{1+\gamma}\left[\frac{F_1(g)}{\kappa-\gamma-1}\right]$.

proportional to the market-determined cutoff:

$$\bar{z}^{opt} = g^{opt}(\kappa, \gamma, \eta)z^* \qquad (16)$$

If we interpret z^* as a market determined preference for quality, markets with higher preference for quality have higher optimal quality standards while markets with a lower preference for quality have a lower optimal level of $\bar{z}$. To derive some quantitative intuition for the result, let us focus on the IA case, in which z^* is a constant. For $\kappa = 5$ and $\gamma = 1$, welfare is maximized at $g = 1.41$: the government sets a standard which reduces the probability of a firm being active by $|1.41^{-5} - 1| = 82\%$ relative to the market allocation.[32]

3.4 Discussion

The most direct way to interpret how the quality standard alters welfare is to compare two separate channels. First, a higher standard lowers the number of varieties available, which lowers welfare. Second, it raises allocative efficiency, and utility, by raising the measure of average markups in the market allocation closer to the average social markups. That misallocation is reduced when average markups increase might seem counter-intuitive, but in fact allocative efficiency increases as market share is reallocated away from low-quality firms and to high-quality firms, a channel highlighted with productivity heterogeneity in recent work by Edmond et al. (2018), Baqae and Farhi (2017), and Weinberger (2017).

Given that the reason that a minimum quality standard $\bar{z}$ can improve welfare is that the market allocation is inefficient, the rest of the subsection is devoted to understand in detail which distortions are reduced by a standard, and how these differ across the types of preferences. Notice that there are three possible margins through which the market equilibrium is inefficient: entry, selection, and the distribution of markups across active firms. However, the assumption of Pareto distributed quality and monopolistic competition constraints the margins of inefficiency present in our model to the allocation of production across entrants (the latter two).[33]

To understand these two margins, we recap the two biases identified in Dhingra and Morrow (2016) (DM). The first type of distortion is due to lack of appropriability: in making their production decision, firms do not take into account the social gains from an increase in variety. This "appropriation bias" causes an excessive degree of firms' selection, whereby $z^* > z^*_{\text{Pl}}$ all else equal. Firm heterogeneity in market power generates the second distortion:

---

[32]Under homothetic and DA preferences, z^* is a function of $\bar{z}$. Hence, the reduction in the probability of being active becomes $|(\tilde{g})^{-\kappa} - 1|$, where $\tilde{g} = \frac{\bar{z}}{z^*(1)} = g\left[\frac{g^{-\kappa}G_1(g)}{G_1(1)}\right]^{\frac{1}{\kappa - \gamma - \frac{1}{1+\eta}}}$.

[33]The mass of entrants J is always efficient in the market allocation (Arkolakis et al., 2017).

in making their production decision, firms do not take into account how their choice alters production and prices of other firms. This "business stealing" effect (DM and Mankiw and Whinston (1986)) reduces selection below the optimum, i.e. $z^* < z^*_{\text{Pl}}$, because it allows low-quality firms to steal business from high-quality firms.[34] Moreover, the business stealing bias distorts the quantity of production across firms. High-quality firms under-produce as their markups are too high and low quality firms over-produce, relative to the efficient allocation.

The quality standard affects welfare in two opposing directions in (15), both of which can be understood through its effect on markups. First, the standard raises the *average markup* through a composition effect which works purely through a reallocation of market shares and bring the economy closer to the socially optimal average markup.[35] The standard eliminates low-quality firms, reducing the distortion that affects selection, and furthermore causes a reallocation of production towards high-quality firms, therefore reducing the distortion on the distribution of quantities produced. These are the two inefficiency margins discussed above. Second, there are the opposing effects that depend on the number of firms. As discussed above, the standard can reduce competition and thus raises the markup of *each surviving firm*. The first term of (14) shows the competitive effect combined with the volume of production aggregator, so that for any value of η welfare is reduced as the number of varieties is reduced. The composition effect dominates for any η.[36] In the following paragraphs, we describe these market inefficiencies that emerge for each of the three specific cases of GTP preferences. To do so, we compare the main variables of interest between the social planner's allocation and the market's allocation, with details once again relegated to the appendix.

IA Preferences Under IA preferences ($\eta = -1$), the market allocation always generates too little selection in the market. The ratio of the planner's quality cutoff relative to the market cutoff is always greater than one: $\left(\frac{z^*_p}{z^*_m(1)}\right)_{IA} = \frac{\kappa - \gamma}{\kappa - \gamma - 1} > 1$. As a result, low-quality firms overproduce and high-quality firms underproduce relative to the planner's allocation. The extent of the business stealing bias, measured by the ratio $\left(\frac{z^*_p}{z^*_m(1)}\right)_{IA}$, is increasing in the dispersion of quality (inverse of κ), and is increasing with the curvature of demand γ. As a result, the optimal level of g decreases in κ and increases in γ.

The quality standard reduces the business stealing bias, by forcing the exit of low quality firms and increasing the production of surviving firms. Although markups of surviving firms do not change, the average markup in the economy increases as the surviving firms have

---

[34]The Dhingra and Morrow (2016) results are in fact applicable to our framework with firms differentiated in quality instead of productivity.

[35]The social planner chooses to equalize markups across firms at $m = \frac{\kappa - \gamma}{\kappa - \gamma - 1}$.

[36]We note, the quality standard is not first-best. It raises expected profits, which induces too much entry, and cannot bring the economy to the efficient allocation.

higher markups.

DA Preferences Under DA preferences $(\eta \to \infty)$, the market allocation generates too little selection in the market, provided that $\gamma > 0$ and, thus, demand is not fully rigid. The ratio of the planner's cutoff to the market cutoff is $\left(\frac{z_p^*}{z_m^*(1)}\right)_{DA} = \left(1 + \frac{1}{\gamma}\right)^{\frac{\gamma}{\kappa - \gamma}} \geq 1$. For $\gamma > 0$, a quality standard improves welfare, by reducing the business stealing bias. For $\gamma = 0$, the bias disappears and the standard cannot improve welfare. The main difference relative to the IA case is that, under DA preferences, markups of surviving firms increase with the standard. As the standard reduces the number of firms in the market, the lower competitive pressure allows for surviving firms to charge higher markups, limiting the benefits of the standard.

Homothetic Preferences Under homothetic preferences $(\eta = 0)$, the ratio of the planner's cutoff relative to the market cutoff is $\left(\frac{z_p^*}{z_m^*(1)}\right)_{H} = \left(1 + \frac{1}{\gamma}\right)^{\frac{\gamma}{\kappa - \gamma - 1}} \left(1 - \frac{1}{\kappa - \gamma}\right)^{\frac{1}{\kappa - \gamma - 1}}$, and it could be smaller or greater than one depending on the parameters of the model.[37] In the presence of business stealing bias the effects of a standard are qualitatively similar to the DA case.

In the presence of too much selection, we find that a quality standard can still improve welfare, altough by a somewhat smaller magnitude relative to the case in which there is too little selection. The reason for this seemingly surprising result is that the market allocation generates a markup distribution that is different from the constant markup that a planner would choose. In particular, markups are on average too small in the market relative to the planner's allocation. The quality standard improves upon such misallocation, despite exacerbating the already too high level of selection. Therefore, one important conclusion from our analysis is that the market distortions are driven entirely by the presence of variable markups, and exist in both homothetic and non-homothetic preferences.

Optimal Standard Across Preferences Figure 3 shows a ranking of the optimal degree of restrictiveness of the standard g across preferences. In particular, $g_{IA}^{opt} > g_{DA}^{opt} > g_{H}^{opt}$. The reason for this ranking is related to the elasticity of the market cutoff with respect to market size $\frac{\partial \ln z^*}{\partial \ln L}$, which controls how firms adjust their markups in response to changes in the number of competitors.

---

[37]There is too little selection in the market, if $\kappa > \gamma + \left(1 - \left(1 + \frac{1}{\gamma}\right)^{-\gamma}\right)^{-1}$. Since regularity conditions imply that $\kappa > \gamma + 1$, there is a region for small enough κ, in which the market allocation generates too much selection. For instance, for the linear case $\gamma = 1$, there is too much selection if $\kappa \in (2, 3)$. Such a case is not quantitatively relevant: in the empirical section we verified that it only occurs in one industry.

As the standard reduces the number of firms active in the market, it generate an increase in firm's markups if $\frac{\partial \ln z^*}{\partial \ln L} < 0$. Under IA preferences, such an elasticity is zero and, thus, the optimal standard is the most restrictive. Under DA and homothetic preferences, the reduction in the number of firms generate increases in markups. Such an increases are the largest under homothetic preferences. Hence, the optimal standard is the smallest under homothetic preferences, and it is at an intermediate level under DA preferences.[38]

Figure 3: Optimal g Across Preferences

(a) As a function of γ **(b)** As a function of κ
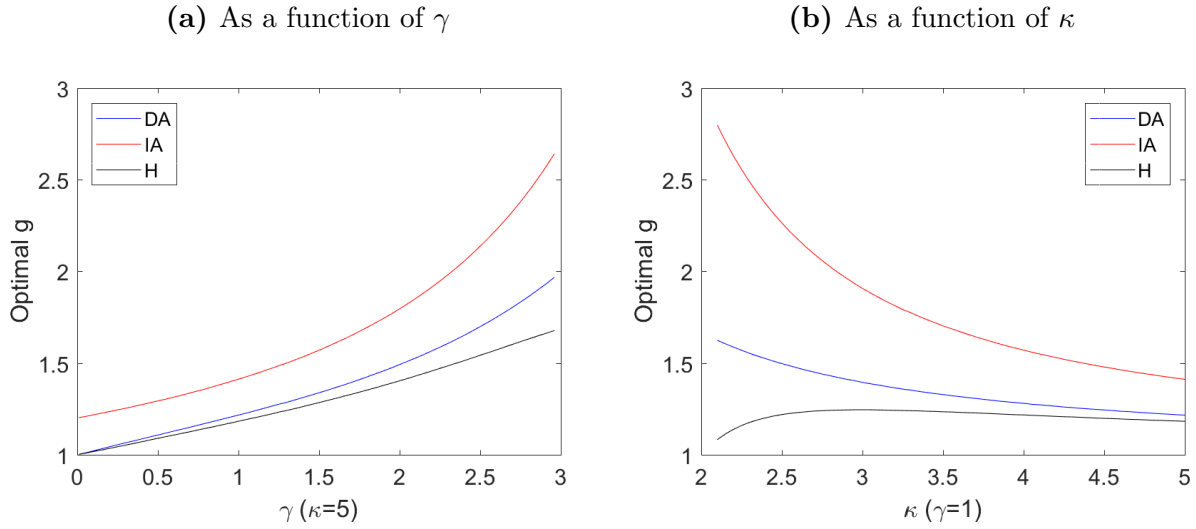

3.5 The Effect of Trade on the Optimal Standard

The purpose of this section is to study whether international trade modifies the optimal level of a quality standard. Given the secular decline in tariffs and traditional non-tariff measures, technical measures are subject of debates over trade agreements (Baldwin et al., 2000), and of several concerns raised at the WTO (Fontagné et al., 2015).

To address the policy debates, we consider a world made of two identical economies, in which exports require an iceberg trade cost τ. As the two countries are identical, we can normalize per capita income and wages to one in both countries. We assume that the two countries decide a common minimum quality requirement $\bar{z}$, which holds in each nation, and we study how different levels of the iceberg trade cost τ affect the optimal level of $\bar{z}$. Thus, we abstract from political economy issues — as well as a complicated non-cooperative game — that would arise if each country were to choose its own optimal level of $\bar{z}$.

---

[38]The ranking of optimal g as a function of the degree by which markups depend on the number of competitors is respected across other preferences not included in GTP. In the online appendix, we provide a detailed discussion of the addilog preferences (Bertoletti et al., 2017), Benassy-CES (Benassy, 1996), Quadratic Mean of Order R (Feenstra, 2014), and Stone-Geary (Simonovska, 2015).

As in a standard Melitz (2003) model, the presence of iceberg trade costs divides firms into exporters and non-exporters. Only high-quality firms are exporters, since their quality level is large enough to sell their goods abroad. Details are in appendix 6.2.7. Let z_D^* and $z_X^* = \tau z_D^*$ denote the market quality cutoff for the domestic and export market. Similarly to the closed economy case, let $g = \frac{\bar{z}}{z_D^*}$ be a measure of the restrictiveness of the quality standard. The effect of g on the selection of firms exhibits a discontinuity. In particular, for $g \in [1, \tau]$, the quality standard only affects low-quality non-exporters. On the other hand, for $g \in [\tau, \infty)$, the standard is so restrictive that the only firms able to remain active are high-quality exporters.

How does the level of international openness affect the optimal minimum quality requirement? To answer to this question, we compute the optimal $\bar{g}^{opt}$ for different levels of τ. As shown in figure 4, lower trade costs reduce the optimal quality requirement[39].

Under homothetic and DA preferences, a reduction in trade costs increases the market selection in the domestic economy without a standard, namely z_D^* increases. Trade forces some of the firms of low-quality out of the market, in a similar fashion to the quality standard. Hence, a reduction of trade costs and an increase in the restrictiveness of the standards are two policies that achieve the same welfare result. Therefore, the larger the reduction in trade costs, the larger the reduction in the restrictiveness of standards.

Under IA preferences, the domestic cutoff z_D^* is not affected by trade costs. However, it is reassuring that even in this extreme case where there is no selection effect that drives domestic firms out of the market in response to a trade liberalization (due to the assumption of IA preferences), lower iceberg trade costs still improve allocative efficiency. The rationalization of this finding comes through production reallocation. As trade costs decline, export production increases. Although there are the same number of domestic varieties available, these now compete with foreign varieties, which reallocates production towards high-quality goods. Therefore, the level of distortions is *lower* in a more open economy, alleviating the need for a standard. We believe this rationalizes a dual approach for policymakers: pushing towards lower trade costs while lowering the restrictiveness of quality standards.

---

[39]We restrict τ so that $g^{opt} \in [1, \tau]$, and the restriction only affects non-exporters. Although it is theoretically possible for the standard to force out of the market all non-exporters, it is not a realistic outcome and, thus, we ignore it.

Figure 4: Optimal Requirement and Trade Costs
4 Model Estimation

In the theoretical framework, we incorporate technical measures into an economy with firm heterogeneity, so that the measure of producing firms and the sales of these firms depend on the level of regulatory restrictiveness in the industry plus demand and supply parameters. Next, we use the model to estimate the regulatory restrictiveness of Chilean industries by matching the empirical sales distribution constructed with the firm data described in section 2.

We do not require any data on the number of technical measures/standards imposed, but instead employ a simulated method of moments procedure that estimates (g, κ, γ) to minimize the difference between percentiles of the model and data sales distribution. We run this procedure for a cross-section of industries and repeat it across multiple years. The estimation yields not only an implied level of restrictiveness – which we call g in the model – but also the optimal level of restrictiveness at the industry level given the productivity distribution and demand curvature parameters. Hence, we provide a meaningful interpretation of how many industries appear to be *too restrictive* as characterized by the structure of the model, even allowing for large optimal standards. Previewing the results, we find that many industries appear very restrictive up until 2000, but not in 2005.

4.1 Strategy

In this section, we describe how to quantify the restrictiveness in a market by using the structural model described in the previous section. The goal is to estimate the parameter set (g, κ, γ) for each industry, as these are enough to characterize the "restrictiveness" of an industry as given by g/g^{opt}. We solve the model via simulation because the moments in the model that pin down these parameters are created using simulated firms. In other words, for a guess of the parameters, we simulate firm-level outcomes and attempt to reproduce moments from the empirical domestic sales distribution. The steps taken to produce the quantitative analysis are described in the following paragraphs.

The first step is to simulate the continuum of firms that exist in the model. We discretize the continuum of firms in the model by simulating a large enough draw so as to best approximate the entire continuum. We follow the insights of Eaton et al. (2011) that were recently applied in Jung et al. (forthcoming), and relabel firm-level indicators that can be simulated from a parameter-free uniform distribution. Recall that the pdf of the quality distribution is given by $g(z) = \frac{\kappa b^\kappa}{z^{\kappa+1}}$. We draw 500,000 realizations of the uniform distribution on the [0; 1] domain, $U \sim [0; 1]$, we order them in increasing order, and find the maximum realization, denoted by u_{max}. Then, the firm quality indicator is $z = (u/u_{max})^{-1/\kappa} z^*$. Given that the market quality cutoff (z^*) is a constant in the IA case, we normalize this to one.[40] By construction, $z \in [1, \infty]$, and hence all draws have positive demand in the case where there is no government imposed quality standard. Given that there exists restrictions on the survival of low-quality firms, the set of producing firms is chosen from $z \in [g, \infty]$.

We then identify the parameters in the model through an over-identification strategy that targets 99 moments from the empirical domestic sales distribution. Given a set of potential producers in the simulation, namely those with $z > g$, we compute firm revenues normalized by mean revenues:

$$\tilde{r}(z|z > g) = \frac{r}{\bar{r}} = (G_2(g))^{-1} \left(\frac{z}{z^*} - 1\right)^\gamma \left(\frac{z}{z^*} + \gamma\right) \tag{17}$$

where $F_1(g)$ and $F_2(g)$ are two hypergeometric functions described in Footnote 28.[41] After conditioning on active firms, relative sales are independent of η.[42]

The theoretical relative sales are matched to their counterpart in the data in order to

---

[40]In the non-IA cases, we compute the new z^* for any given guess of the standard.

[41]In practical terms, we use the matlab function *hypergeom* to compute these functions.

[42]The set of active firms does depend on η as the market determined cutoff moves with g, however we find that the estimated parameters across the types of preferences are almost identical. Of course, the predicted optimal standard is sensitive to the types of preferences, and in the Appendix we compare the compare the results between the IA and DA cases.

identify the model parameters in an approach that follows Sager and Timoshenko (2017). Let $F_q^m(g, \kappa, \gamma) = \log(\tilde{r})_q$ be the q-th quantile of the simulated log domestic sales distribution. Then, let F_q^d denote the corresponding value of the empirical CDF of the log sales distribution. Our identification consists of choosing the parameter set that minimizes the sum of the squared errors between empirical and theoretical quantiles:

$$\min_{g,\kappa,\gamma} \sum_{q=1}^{99} \left(F_q^d - F_q^m(g, \kappa, \gamma) \right)^2. \tag{18}$$

Finally, we compute bootstrap standard errors by running the estimation above 100 times, each time taking a bootstrap sample of the data. We take the average parameter estimates to compute $(\hat{g}, \hat{\kappa}, \hat{\gamma})$, and use the standard deviation of estimates to compute a 95% confidence interval.

The strategy to estimate the parameter set $(\hat{g}, \hat{\kappa}, \hat{\gamma})$ is based on the separate ways that each parameter is identified within the sales distribution. κ governs the shape of the quality distribution, which is proportional to the shape in the sales distribution only in special cases (Mrazova et al., 2017), which do not apply to our GTP specification. The divergence in the sales and quality distribution is due to the distribution of markups. Since firm markup levels are a function of γ (see (8)), this parameter affects the mapping from the quality to the sales distribution and is not collinear with κ.[43] Finally, as is argued above, the standard not only eliminates low-quality firms but reallocates resources to higher-quality firms. Therefore, relative sales across percentiles of the sales distribution are a function of g. For this reason we use a general strategy to match sales across the firm distribution, with each parameter being identified by different parts of the distribution.

We employ the strategy above for each 4-digit ISIC (revision 3) industry by year. Although there are about 100 industries in this level of classification, we only keep industries in which there are at least 35 firms in 1995, which allows us to estimate restrictiveness for 40 industries. We construct a restrictiveness index (RI) using the estimated parameters:

$$RI_{it} = \frac{\hat{g}_{it}}{\hat{g}_{it}^{opt}(\hat{\kappa}_{it}, \hat{\gamma}_{it})}. \tag{19}$$

The interpretation of this index is slightly different than the technical measures in section 2, as it captures any industry characteristics that limits the survival of firms at the bottom of the sales distribution. We choose the indirectly additive model as the benchmark because of the fact that it yields the most conservative estimate of whether an industry is *too* restrictive.[44]

---

[43] As is not the case, for example, if preferences were CES and the distribution of quality is Pareto.

[44] This is due to its weaker selection effects. Notice that the optimal standard simply shifts downwards for

However, we can interpret it as an *upper bound* for which policymakers can view an industry as overly regulated. In addition, we compute the optimal standard in the closed economy, whereas trade would reduce the need for regulations. The restrictiveness index is therefore a conservative measure of industries that appear to be too highly regulated, given that is allows for a wide variety of measures – for example one that is meant to be protectionist in the guise of a quality standard – and the fact that the theoretical optimal standard is an upper bound.

4.2 Estimation Results

Before we discuss the industry level restrictiveness, we provide evidence that the model is able to produce a close fit with the empirical sales distribution. For expositional purposes, the procedure in the previous subsection is employed for all firms so that the parameter set $(\hat{g}, \hat{\kappa}, \hat{\gamma})$ is estimated to fit the cross-section of the universe of Chilean manufacturing firms in each year. Figure 5 displays the model and empirical sales distributions for 1995, 2000, and 2005. The estimated level of the quality standard had a 95% confidence interval above one in every year, with the standard peaking at 1.13 (with standard error of .01) through 1998-2000, before dropping every year thereafter to 1.02 in 2007 (standard error .002). The figure also reports the values of the demand and supply parameters jointly estimated with the quality standard. The parameter for demand curvature ranges between 1.3 and 2.4, rejecting the simple linear demand model in every year. For example, in 1995, $\hat{\gamma}$ is 1.92 with a 95% confidence interval in (1.63,2.21). The Pareto shape parameter varies between 4-5 for the majority of the sample (consistent with estimates in Jung et al. (forthcoming) and Simonovska and Waugh (2014)), and below 3 after 2004. For example, in 1995, $\hat{\kappa}$ is 4.49 with a 95% confidence interval in (3.37,5.6). The Figure also allows us to visually compare the model and empirical sales distributions, which are reassuringly close. Finally, as a sanity check, the model implied average markups are 14%, 12%, and 31% in the three displayed years. These are very much in line with empirical markup estimates: in Chile we find that weighted average markups in the same three years are 22%, 20%, and 38%.[45]

The reason for the changes across time are due to structural changes in the empirical sales distribution. Although dispersion measures are roughly constant between 1995 and 2003, there is a clear expansion of the largest firms after 2003. For example, we find that the

---

other preferences where $\eta \geq 0$. Thus, in those cases, more industries would appear too restrictive (results in the appendix).

[45]These are based on estimating markups using the De Loecker and Warzynski (2012) procedure and using material inputs as the variable input. We take a weighted average using the firms' share of total employment in the economy.

ratio of sales between exporters and non-exporters gets larger[46], differences in sales between firms at certain percentiles become larger, skewness decreases (longer left tail), and average markups increase (as reported above). This could reflect an expansion of the largest firms, or smaller firms at the bottom of the distribution. We find that the former is more apparent in the sales data, and point to the effect of trade in the industry analysis below.

Figure 5: Log Domestic Sales Distribution: Model VS Data
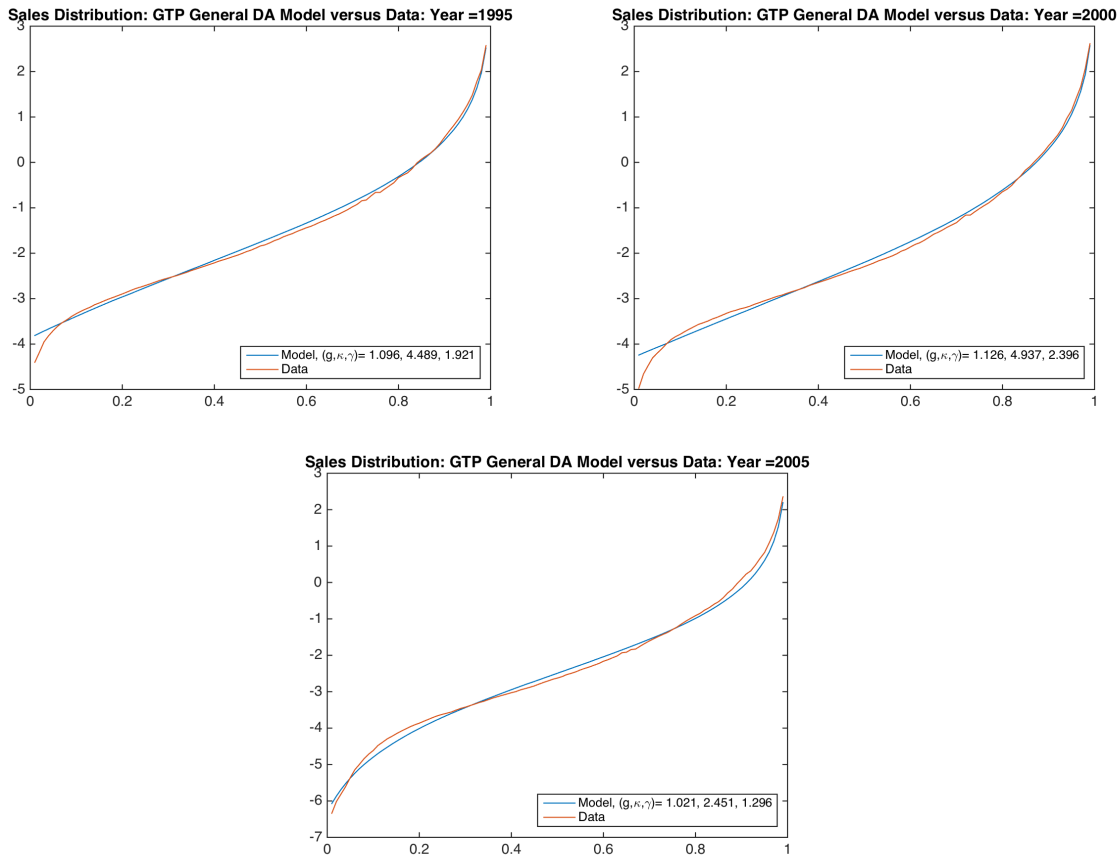

Notes: Each Figure plots the CDF of the log sales distribution in the data (red) versus the simulated distribution given the estimated parameters. The model is estimated using the universe of manufacturing firms in each year. The 95% confidence intervals for the parameters in each of the three years are: $\hat{g} = (1.08, 1.11), (1.1, 1.15), (1.01, 1.03)$; $\hat{\kappa} = (3.37, 5.6), (3.59, 6.29), (2.12, 2.78)$; $\hat{\gamma} = (1.63, 2.21), (2.04, 2.75), (1.17, 1.42)$.

Next, we report robustness exercises by again relying on aggregate annual data to make the exposition simple. The estimation above takes a general approach in terms of attempting to match the whole sales distribution instead of specific moments within the distribution. As a robustness check, we have applied a similar SMM procedure with specific moments from the sales distribution that are pinned down by our parameters of interest. We construct 4

---

[46]If we were to compare the average sales of firms above the median in domestic sales versus below the median, the results are similar.

moments: i) the sales advantage of "high-quality" relative to "low-quality" firms[47]; ii) the skewness of the distribution which captures the fact that a standard reallocates sales away from the smallest firms; and iii) two differences: $\log(\tilde{r})_{99} - \log(\tilde{r})_{90}$ and $\log(\tilde{r})_{90} - \log(\tilde{r})_{10}$.[48] We plot the simulated sales distribution analogous to the Figure above in Appendix 6.3 and report the estimated parameters. We do not find large discrepancies with our benchmark strategy: $\hat{g}$ is very similar and has the same time series patterns, as do the other two parameters. However, in the alternative calibration, the fit with the data distribution is clearly not as close.

A separate robustness test is to fix the demand and/or supply parameters to estimate restrictiveness, with full results in the Appendix. First, we $\gamma = 1$ and estimate the remaining two parameters, in case there is collinearity with the shape of the quality distribution. Again, we report the results in Appendix 6.3, and show that the time series pattern hold from the baseline estimation. However, there is a shift downwards of κ and g, as the restriction on the demand curvature requires more small firms and a larger dispersion in quality to match the dispersion in sales. However, the comparison of the sales distribution in the estimation relative to the data make it clear that this specification is not able to match the dispersion in sales.[49] This is apparent in the implied average markups, which are 39%, 46%, and 51%, clearly larger than reasonable markup estimates.[50] Second, we estimate *only* the restrictiveness parameter, and assume κ (set to 4) and γ (set to 1.8), are deep parameters constant over time. Still, $\hat{g}$ ranges between 1.04 and 1.1 with similar time-series movements.

Finally, we move on to the industry analysis to highlight the heterogeneity across industries. An intuitive measure to report is the reduction in the survival probability in the presence of the current technical measures. In the Appendix we report the reduced probability for each industry in 1995, 2000 and 2005 – calculated as $(1 - \hat{g}^{-\hat{\kappa}})$. On average, this is

---

[47]This moment is related to that used to identify the elasticity of substitution in Bernard et al. (2003). Instead of comparing exporters and non-exporters, we compare firms above and below the median in sales.

[48]We point out that moments from other distributions, such as markups and value added, are not used because the data does not allow us to differentiate between exported and domestic components.

[49]Jung et al. (forthcoming) estimate the Melitz and Ottaviano (2008) separable model and argue that the linear demand assumption predicts a sales distribution with too little dispersion (given their preferred estimate of κ as estimated using a general demand curvature). In fact, we confirm this as the estimation with $\gamma = 1$ predicts too few sales on the right tail, even as $\hat{\kappa}$ is lower, in the range of 2 to 3. Notice that our main estimation implies a larger substitution parameter, which reduces the market power that each firm possesses. This raises the sales of the largest firms as demand is more elastic relative to the linear demand case.

[50]As a further robustness check, we have also estimated the general Addilog model of Bertoletti and Etro (2017) and the linear, separable Melitz and Ottaviano (2008) model. The former is very similar to the IA case in our GTP framework, while the former is very similar to the DA case with $\gamma = 1$ in our framework. Therefore, these are variations to our main estimation and our robustness exercise. We found the results are almost identical to those two estimations, and we make the results available upon request. For more details on how to fit our quality differentiation within these models, see the Web Appendix.

39% in 1995, 40% in 2000, and drops to 26% in 2005. This is consistent with what we see in the Figures above, where the restrictiveness at the economy wide-level seems to decrease in 2005. There is also large heterogeneity across industries. The most restrictive industries consistently across the years – Motor Vehicles, Books/Journals, Machinery and Other Metals, Pharmaceutical, and various food industries – averaged over 50% lower survival probability. On the other hand, there are industries such as Apparel and Furniture that hover around 10% in reduced probability across all years.[51]

4.3 Restrictiveness of Standards and Optimal Standard

To evaluate the restrictiveness of technical measures more formally, we compare the estimated level of restrictiveness with the optimal standard predicted by our model. For each industry-year, we compute (19), which recall is interpreted as a conservative measure of the restrictiveness of an industry since we use the highest possible optimal standard. We find that there are several industries that appear too restrictive but that number has changed over the years. As in the estimation for the universe of firms, the level of restrictiveness increases from 1995 to 2000, but drops significantly in 2005.

In order to capture the level of restrictiveness and the changes over the years at the industry level, Figure 6 plots the RI in 1995, 2000, and 2005 for each industry, sorted from largest to smallest. Plots that result from the estimation of DA preferences and assuming a fixed cost for the standard are in the Appendix – in both cases the optimal standard is merely shifted downwards. For each industry-year the 95% confidence interval is plotted using the estimated standard error for g in the calibration. Recall that a value above one is evidence of *too much* restrictiveness in an industry. These industries are highlighted in the figure with a red color, where we highlight any industry where the confidence interval includes a ratio of one or above. In 1995, 11 out of 38 industries are too restrictive by this definition, although there are several industries that hover around 1.[52] In 2000, there are 12 too-restrictive industries, though a similar number are clustered around an RI index of 1. Therefore, even with the conservative measure of the optimal standard, 32% of industries are within the confidence interval of being "too restrictive". We take this as evidence that Chilean manufacturing industries appear to be overly regulated – either through protectionism or other types of technical measures – at the start of the century.[53] However, this restrictiveness

---

[51]Certain industries contain large variances that suggest the estimation method was not stable in those cases. In the analysis of time variation below, we eliminate "Other Publishing" and "Bakery" which have massive decreases in restrictiveness.

[52]The noise in the estimation can affect whether an industry fits within our definition of possibly too restrictive.

[53]Some industries might fit into this category due only to the large variance in the estimation. However,

drops precipitously over the next few years.

The third panel in Figure 6 shows that in 2005 only 5 out of 38 industries (13%) were overly regulated, and it is clear many more industries drop far below the cutoff.[54] Although this estimation does not allow us to break down the restrictiveness into specific measures, it is likely that a greater openness to trade contributed to the reduction. In the Appendix (Figure 25), we plot the total value of exports and imports relative to GDP[55], which suggests that the economy becomes especially more open after 2000. There is also evidence based on the number of trade deals signed by Chile during this time period. Chile signed free trade agreements with the EU in 2002, with the United States and Korea in 2004, and with China in 2005.[56] It also lowered its across-the-board tariffs to 6% for all countries with which it does not have an agreement. In the bottom panel of Figure 25 we plot average applied tariff rates (weighted by industry import flows) and the terms of trade (provided by the World Development Indicators). Tariffs begin their decline in 1999, dropping from 11% to 2% in 2007. There is a large terms of trade appreciation after 2001 – due to the price of copper – which would create opportunities for importers to enter the Chilean market.[57]

In Figure 7, we present the log difference in the restrictiveness index between 2000 and 2005 plotted against an industry openness measure.[58] There is a negative correlation between the changes in restrictiveness and openness of the industry. Recall that freer trade provides a welfare-enhancing reallocation to high-quality firms, diminishing the necessity of the standards. It eliminates the smallest firms, likely making the sales of the smallest surviving firms larger, but also raises the sales of firms in the right tail. For example, take the meat industry (ISIC 1511), one of the most open industries in Chile. The ratio of average domestic sales of exporters relative to average domestic sales of non-exporters is 2.80 in 2000, and increases to 3.44 in 2005.[59] The results suggest that the expansion of the large firms is what drives the the estimated lower restrictiveness of industries (and is also consistent with a lower estimated κ). Although the contemporaneous correlation is only suggestive evidence, it does reinforce our claim in the introduction: the rationale introduced in this paper is not

this is only obvious in the "Other Manufacturing" and "Journals industries. 9 out of 40 industries would still be a large number of industries.

[54]In a time series, it is also evident that the restrictiveness drops gradually over the years from 2000.

[55]We also exclude the basic metals industry given the very large spike in the price of copper between 2004 and 2006.

[56]2004 is when all tariffs were reduced with Korea and the US. In the FTA with the EU, tariffs *started* to be reduced in 2006.

[57]An examination of the real effective exchange rate also displays a sustained appreciation in the years between 2003 and 2006.

[58]Openness is defined as the sum of imports and exports over total sales.

[59]The values are similar for all years between 1995-2003, and 2004-2007. Furthermore, a similar pattern holds across many open industries.

to call for protectionism, but supports a dual approach of lowering trade costs while reducing unnecessary restrictiveness of quality standards.

5   Conclusion

We have provided a rationale for technical measures to trade that does not rely on the existence of negative externalities nor the benefits of quality upgrading. The main contribution of this paper is to provide a framework under which technical measures can improve welfare by reducing the business stealing bias. When such a bias occurs, too many low-quality firms are active in a market. Thus, technical measures that force low-quality firms out of the market can be welfare improving. In order to motivate the welfare-enhancing reallocation that occurs in the model, we rely on a panel of Chilean manufacturing firms and compare the distribution of firm sales across industries that differ in their level of regulation. Our findings that non-tariff measures skews domestic sales towards high-quality firms complements the rest of the literature that has found these measures to reduce the extensive margin of export flows.

Moreover, we have shown that trade openness reduces the optimal degree of restrictiveness of quality standards. In fact, openness appears to have reduced the regulatory burden in Chilean manufacturing. We estimate the model to fit the observed distribution of domestic sales and conduct a policy-relevant evaluation that compares the estimated level of restrictiveness with the optimal standard as predicted by our model. Although industries appear heavily regulated up until 2000, this is not the case in 2005 and there is suggestive evidence that it is driven by more open industries. Hence, this paper supports the efforts of the WTO to improve the Technical Barriers to Trade Agreement, along with traditional trade agreements.

Figure 6: Restrictiveness of Standard and Upper Bound: 1995, 2000, and 2005.
Figure 7: Industry Openness vs Log Difference in Industry Restrictiveness (2000 to 2005)

Notes: This Figure plots Industry Openness versus the log change in the restrictiveness index between 2000 and 2005. Openness (x-axis) is defined as the sum of imports and exports over total sales. The y-axis is the log change in the restrictiveness index between 2000 and 2005. There are a total of 34 industries in the plot, as we drop industries with openness above a ratio of 4. The result is robust to allowing for industries with an even larger ratio, but we believe a cutoff is necessary because, for example, the "Other Manufacturing" industry has an openness ratio more than 60 times larger than the median industry. The slope of the best fit line is -.2.

6 Appendix

6.1 Motivational Evidence

Table 2: Top 25 Most Regulated Industries

Rank	Ranked by Coverage		Ranked by Total Number	
	ISIC	Industry Name	ISIC	Industry Name
1	2421	Pesticides	2411	Basic chemicals
2	1520	Dairy products	1512	Fish products
3	1531	Grain products	1511	Meat products
4	1552	Wine	1711	Textiles
5	1511	Meat products	1513	Fruit and vegetables
6	1513	Fruit and vegetables	1810	Wearing apparel
7	1551	Alcohol production	2423	Pharmaceuticals
8	1554	Soft drinks	1514	Oils and fats
9	1532	Starch products	1520	Dairy products
10	1533	Animal feeds	1549	Other Food
11	1549	Other Food	1531	Grain products
12	1512	Fish products	2922	Machine tools
13	1514	Oils and fats	2429	Other chemicals
14	2424	Cleaning products	2930	Domestic appliances
15	2010	Wood	2520	Plastic
16	1544	Farinaceous products	3210	Electronic components
17	1543	Candy bars	2424	Cleaning products
18	2021	Plywood, etc	2919	Other general purpose machinery
19	3230	TV and radio receivers	3190	Other electrical equipment
20	3150	Lighting equipment	3230	TV and radio receivers
21	3190	Other electrical equipment	3110	Electric motors
22	2912	Pumps	1532	Starch products
23	3311	Medical equipment	2010	Wood
24	2423	Pharmaceuticals	3311	Medical equipment
25	2023	Wooden containers	2912	Pumps

Ranked by Coverage refers to the standard approach of normalizing the number of regulations in an industry by the number of products in the industry. We compare this with the total number of regulated products in an industry (Ranked by Total Number).

Table 3: Correlation of Quality with TFP (top) and Size (bottom) across Firms

	Quality Proxy					
	log(K/L)	log(W/L)	log(M/L)	log(K/L)	log(W/L)	log(M/L)
Log TFP	0.532***	0.436***	1.323***			
	(0.110)	(0.036)	(0.068)			
Log Labor Productivity				0.646***	0.349***	0.606***
				(0.030)	(0.012)	(0.030)
Fixed Effects	Industry-Year	Industry-Year	Industry-Year	Industry-Year	Industry-Year	Industry-Year
# Observations	63790	63785	63790	61779	65483	65441

	Quality Proxy		
	(K/L)	(W/L)	(M/L)
Log Size	0.464***	0.227***	0.473***
	(0.015)	(0.005)	(0.014)
Fixed Effects	Industry-Year	Industry-Year	Industry-Year
# Observations	64894	68864	67993

Each column is intended to relate the correlation between separate measures of quality with productivity and size. The top table displays results for two different measures of productivity: log TFP estimated from a Translog production function using the procedure outlined in **?**, and a simple measure of logged value added per worker. The bottom panel displays results for the relationship between quality and log sales. Quality is proxied by (logged) capital per worker, total wages per worker, and input expenditure per worker respectively. In all specifications we use the full panel of firm-year observations and include industry-year fixed effects so that we are only capturing within industry-year relationships. We cluster the standard errors at the industry level.

Table 4: Firm Sales Heterogeneity - by NTMs in Industry - Repeated Cross-Sections

	Domestic Sales

Fixed Effects	Industry-Year	Industry-Year	Industry-Year
R^2	0.362	0.446	0.466
# Observations	59740	59740	59740

The measure of NTMs is at the 4 digit ISIC industry level. The total number of measures in each industry-year are totaled and then divided by the number of HS6 products in the industry. Each row interacts the NTM measure with a different proxy for quality. In all specifications we include an interaction of industry openness with the quality indicator, an interaction of the quality indicator measure with the industry import tariff, and an interaction of the quality indicator measure with the industry trade elasticity (Broda and Weinstein (2006)). We include only industry-year interacted fixed effects. We cluster the standard errors at the industry level.

Table 5: Firm Sales (top) and Survival (bottom) Heterogeneity- by NTMs in Industry - IV Results

	Domestic Sales			Survival		
	(IV)	(IV)	(IV)	(IV)	(IV)	(IV)
TM*Quality (Capital/L)	0.034**			0.002		
	(0.016)			(0.011)		
TM*Quality (Wage/L)		0.046***			0.031***	
		(0.016)			(0.011)	
TM*Quality (InputValue/L)			0.006			0.002
			(0.016)			(0.011)
F-stat (first stage)	1745.11	1731.37	1744.89	1862.60	1862.60	1864.97
# Observations	44220	44220	43789	69679	69679	68924
Fixed Effects	Firm, I-Y	Firm, I-Y	Firm, I-Y	Firm, I-Y	Firm, I-Y	Firm, I-Y

In each case, the main interaction is instrumented using the interaction of the same quality indicator but with the NTM measure of Peru. The measure of NTMs is at the 4 digit ISIC industry level. The total number of measures in each industry-year are totaled and then divided by the number of HS6 products in the industry. Each row interacts the NTM measure with a different proxy for quality. In all specifications we include an interaction of industry openness with the quality indicator, an interaction of the quality indicator measure with the industry import tariff, plus firm and industry-year interacted fixed effects.

# Observations	44220	44220	43789	69679	69679	68924

In this table we conduct the specification displayed in (1), but *for specific types of Non-Tariff Measures*. In the top panel we allow technical measure for the SPS chapter only, but drop those geared towards imports. In the middle panel we allow technical measure for the TBT chapter only, but drop those geared towards imports. In the bottom panel we include "A1" and "B1" technical measures as classified by TRAINS. These are the ones we drop from the SPS and TBT measures as they are the types of measures which are more likely to affect importers and not domestic firms. The NTM measures are aggregated to the 4 digit ISIC industry level. The total number of measures in each industry-year are summed and then divided by the number of HS6 products in the industry. Each row interacts the NTM measure with a dummy for quality, where quality is proxied by capital per worker, total wages per worker, and input expenditure per worker respectively. Firms are high-quality if the quality proxy is above the median in that industry in 1995. In all specifications we include an interaction of industry openness with the quality indicator, an interaction of the quality indicator measure with the industry import tariff, plus firm and industry-year interacted fixed effects. We cluster the standard errors at the industry level.

6.2 Model's Derivations

6.2.1 Consumers' Problem

Recall the Generalized Translated Power (GTP) preferences:

$$U = \int_{\Omega} \left(az\xi q(\omega) - \frac{(\xi q(\omega))^{1+\frac{1}{\gamma}}}{1+\frac{1}{\gamma}} \right) d\omega + \frac{\xi^{-\eta} - 1}{\eta} \tag{20}$$

where ξ is a quantity aggregator that is implicitly defined as:

$$\xi^{-\eta} = \int \left(az\xi q(\omega) - (\xi q(\omega))^{1+\frac{1}{\gamma}} \right) d\omega \tag{21}$$

The first order conditions of the consumers' problem are:

$$az\xi - \xi^{1+\frac{1}{\gamma}} q(\omega)^{\frac{1}{\gamma}} + \left[\underbrace{\int \left(azq(\omega) - \xi^{\frac{1}{\gamma}}(q(\omega))^{1+\frac{1}{\gamma}} \right) d\omega - \xi^{-\eta-1}}_{=0 \text{ by } (21)} \right] \frac{\partial \xi}{\partial q(\omega)} = \lambda p(\omega)$$

$$az\xi - \xi^{1+\frac{1}{\gamma}} q(\omega)^{\frac{1}{\gamma}} = \lambda p(\omega) \tag{22}$$

By multyplying both sides of (22) by $q(\omega)$ and integrating across all varieties $\omega \in \Omega$, we obtain the marginal utility of income λ.

$$\lambda = \frac{1}{y} \int \left(az\xi q(\omega) - (\xi q(\omega))^{1+\frac{1}{\gamma}} \right) d\omega = \frac{\xi^{-\eta}}{y} \tag{23}$$

Using (23) in (22) yields the inverse demand:

$$p(\omega) = \frac{\xi}{\lambda} \left[az(\omega) - (\xi q(\omega))^{\frac{1}{\gamma}} \right] = y\xi^{1+\eta} \left[az - (\xi q(\omega))^{\frac{1}{\gamma}} \right] \tag{24}$$

As we consider a closed economy, we normalize per capita income to unity.

6.2.2 Quality Standard and Aggregate Variables

The average profits of firms with $z > \bar{z}$ are:

$$\bar{\pi} = \int_{\bar{z}}^{\infty} \pi(z) \frac{\kappa \bar{z}^{\kappa}}{z^{\kappa+1}} dz =$$

$$= \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma} \right)^{\gamma} \frac{(z^*)^{\gamma}}{\xi} \int_{\bar{z}}^{\infty} \left(\frac{z}{z^*} - 1 \right)^{1+\gamma} \frac{\kappa \bar{z}^{\kappa}}{z^{\kappa+1}} dz =$$

$$= \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma} \right)^{\gamma} \frac{(z^*)^{\gamma}}{\xi} G_1(g) \tag{25}$$

where $G_1(g)$ is a function of κ, γ, and of the restrictiveness of the standard g:

$$G_1(g) = \int_{\bar{z}}^{\infty} \kappa \left(\frac{z}{z^*} - 1\right)^{1+\gamma} \frac{\bar{z}^{\kappa}}{z^{\kappa+1}} dz =$$

$$= \int_{\bar{z}}^{\infty} \kappa \left(1 - \frac{z^*}{z}\right)^{1+\gamma} \frac{\bar{z}^{\kappa}}{(z^*)^{1+\gamma} z^{\kappa-\gamma}} dz =$$

$$= \kappa g^{1+\gamma} \left[\frac{F_1(g)}{\kappa - \gamma - 1} - g^{-1} \frac{F_2(g)}{\kappa - \gamma}\right] \tag{26}$$

$F_1(g)$ and $F_2(g)$ are two hypergeometric functions given by[60]:

$$F_1(g) = {}_2F_1\left[\kappa - \gamma - 1, -\gamma; \kappa - \gamma, g^{-1}\right]$$

$$F_2(g) = {}_2F_1\left[\kappa - \gamma, -\gamma; \kappa - \gamma + 1, g^{-1}\right].$$

The probability of a firm being active is:

$$P(z \geq \bar{z}) = \frac{b^{\kappa}}{\bar{z}^{\kappa}} = \frac{b^{\kappa}}{(z^* g)^{\kappa}} \tag{27}$$

The zero expected profit condition shown in the main text is:

$$P(z \geq \bar{z})\bar{\pi} = f_E$$

$$\frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} \frac{b^{\kappa}}{(z^*)^{\kappa-\gamma} g^{\kappa} \xi} G_1(g) = f_E \tag{28}$$

from which we obtain:

$$(z^*)^{\kappa-\gamma} \xi = \frac{Lcb^{\kappa}}{f_E(1+\gamma)} \left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} g^{-\kappa} G_1(g) \tag{29}$$

Substituting the quality cutoff $z^* = \frac{c}{a}\xi^{-(1+\eta)}$ into (29) yields the quality cutoff z^* and market aggregator ξ as a function of g and model's parameters:

$$z^* = \left[\frac{Lc^{\frac{\eta}{1+\eta}} \gamma^{\gamma} b^{\kappa} a^{\gamma + \frac{1}{1+\eta}}}{f_E(1+\gamma)^{1+\gamma}} g^{-\kappa} G_1(g)\right]^{\frac{1}{\kappa - \gamma - \frac{1}{1+\eta}}} \tag{30}$$

$$\xi = \left[\frac{Lb^{\kappa} a^{\kappa} \gamma^{\gamma}}{f_E(1+\gamma)^{1+\gamma} c^{\kappa-\gamma-1}} g^{-\kappa} G_1(g)\right]^{-\frac{1}{(1+\eta)(\kappa-\gamma)-1}} \tag{31}$$

Firms' average revenues are:

$$\bar{r} = \int_{\bar{z}}^{\infty} r(z) \kappa \frac{\bar{z}^{\kappa}}{z^{\kappa+1}} dz = \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} \frac{(z^*)^{\gamma}}{\xi} G_2(g) \tag{32}$$

---

[60]In practical terms, we use the matlab function *hypergeom* to compute these functions.

where $G_2(g)$ is a function of κ, γ, and g:

$$G_2(g) = \int_{\bar{z}}^{\infty} \kappa \left(\frac{z}{z^*} - 1\right)^{\gamma} \left(\frac{z}{z^*} + \gamma\right) \frac{\bar{z}^{\kappa}}{z^{\kappa+1}} dz =$$

$$= \int_{\bar{z}}^{\infty} \kappa \left(1 - \frac{z^*}{z}\right)^{\gamma} \left(1 + \gamma \frac{z^*}{z}\right) \frac{\bar{z}^{\kappa}}{(z^*)^{1+\gamma} z^{\kappa-\gamma}} dz =$$

$$= \kappa g^{1+\gamma} \left[\frac{F_1(g)}{\kappa - \gamma - 1} + \gamma g^{-1} \frac{F_2(g)}{\kappa - \gamma}\right] \tag{33}$$

Hence, revenues normalized by average revenues, which we use in the calibration exercise, become:

$$\frac{r(z)}{\bar{r}} = (G_2(g))^{-1} \left(\frac{z}{z^*} - 1\right)^{\gamma} \left(\frac{z}{z^*} + \gamma\right) \tag{34}$$

By market clearing:

$$\frac{c}{1+\gamma} \left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} \frac{Jb^{\kappa}}{(z^*)^{\kappa-\gamma} g^{\kappa} \xi} G_2(g) = 1 \tag{35}$$

Dividing (35) by (28) yields the equilibrium mass of entrants, which is independent of η:

$$J = \frac{L}{f_E} \frac{G_1(g)}{G_2(g)} \tag{36}$$

As shown in figure 8, market entry J is increasing in the restrictiveness of the standard.

Figure 8: Effects of a Standard on Entry
6.2.3 Welfare

To derive the utility and the quantity aggregator ξ we need to derive the two integrals in (20) and (21). First, we obtain:

$$\int_{\bar{z}}^{\infty} a\xi z q(z) = a \left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} \frac{Jb^{\kappa}}{(z^*)^{\kappa-\gamma} g^{\kappa}} z^* G_3(g) \tag{37}$$

where $G_3(g)$ is given by:

$$G_3(g) = \int_{\bar{z}}^{\infty} \kappa \frac{z}{z^*} \left(\frac{z}{z^*} - 1\right)^{\gamma} \frac{\bar{z}^{\kappa}}{z^{\kappa+1}} dz =$$

$$= \int_{\bar{z}}^{\infty} \kappa \left(1 - \frac{z^*}{z}\right)^{\gamma} \frac{\bar{z}^{\kappa}}{(z^*)^{1+\gamma} z^{\kappa-\gamma}} dz =$$

$$= \kappa g^{1+\gamma} \left[\frac{F_1(g)}{\kappa - \gamma - 1}\right] \tag{38}$$

Rearranging the market clearing condition,

$$\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma} \frac{Jb^{\kappa}}{(z^*)^{\kappa-\gamma} g^{\kappa} \xi} = \frac{(1+\gamma)\xi}{cG_2(g)} \tag{39}$$

Using (39) into (37) yields:

$$\int_{\bar{z}}^{\infty} a\xi z q(z) = (1+\gamma)\frac{az^*\xi}{c} \left(\frac{G_3(g)}{G_2(g)}\right) \tag{40}$$

Following the same steps, we obtain the second integral:

$$\int_{\bar{z}}^{\infty} (\xi q(z))^{1+\frac{1}{\gamma}} = \left(\frac{a\gamma}{1+\gamma}\right)^{1+\gamma} \frac{Jb^{\kappa}}{(z^*)^{\kappa-\gamma} g^{\kappa}} z^* G_1(g)$$

$$= \frac{az^*\xi}{c} \gamma \left(\frac{G_1(g)}{G_2(g)}\right) \tag{41}$$

Substituting (40) and (41) into the utility function 20 yields:

$$U = \int_{\Omega} \left(az\xi q(\omega) - \frac{(\xi q(\omega))^{1+\frac{1}{\gamma}}}{1 + \frac{1}{\gamma}}\right) d\omega + \frac{\xi^{-\eta} - 1}{\eta}$$

$$= \frac{az^*\xi}{c} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)}\right] + \frac{\xi^{-\eta} - 1}{\eta}$$

By the cutoff condition (6), $\xi^{-\eta} = \frac{a\xi z^*}{c}$. Thus the utility becomes:

$$U = \frac{az^*\xi}{c} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta}\right] - \frac{1}{\eta}$$

Finally, by the cutoff condition, $z^* = \frac{c}{a}\xi^{-1-\eta}$. Thus, the utility becomes:

$$U = \xi^{-\eta} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta}\right] - \frac{1}{\eta} \tag{42}$$

46

Substituting (31) into (42) yields:

$$U = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}g^{-\kappa}G_1(g)\right]^{\frac{\eta}{(1+\eta)(\kappa-\gamma)-1}}\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta}\right] - \frac{1}{\eta} \tag{43}$$

The government chooses $\bar{z}$. The equilibrium value of $z^*(g)$ is determined by the equation that describes the cutoff as a function of $z^*(g)$. The measure of the restrictiveness of the standard as the ratio between $\bar{z}$ and the market cutoff under no restriction $z^*(1)$ is given by:

$$\tilde{g} = \frac{\bar{z}}{z^*(1)} = \frac{\bar{z}}{z^*(g)}\frac{z^*(g)}{z^*(1)} = g\left[\frac{g^{-\kappa}G_1(g)}{G_1(1)}\right]^{\frac{1}{\kappa-\gamma-\frac{1}{1+\eta}}} \tag{44}$$

and exactly equals g under IA preferences $\eta = -1$.

Directly Additive Preferences

The case of DA preferences is obtained by setting $\eta \to \infty$. The utility, market cutoff, and aggregator become:

$$U_{DA} = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}g^{-\kappa}G_1(g)\right]^{\frac{1}{\kappa-\gamma}}\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)}\right] \tag{45}$$

$$z_{DA}^*(g) = \left[\frac{Lc\gamma^\gamma b^\kappa a^\gamma}{f_E(1+\gamma)^{1+\gamma}}g^{-\kappa}G_1(g)\right]^{\frac{1}{\kappa-\gamma}} \tag{46}$$

$$\xi_{DA} = 1 \tag{47}$$

Indirectly Additive Preferences

The case of IA preferences is obtained by setting $\eta = -1$. The utility becomes:

$$U_{IA} = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}g^{-\kappa}G_1(g)\right]\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} - 1\right] + 1 \tag{48}$$

$$z_{IA}^* = \frac{c}{a} \tag{49}$$

$$\xi_{IA} = \frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}g^{-\kappa}G_1(g) \tag{50}$$

Homothetic Preferences

The case of homothetic preferences is obtained by setting $\eta = 0$. The market determined cutoff and aggregator become:

$$z_H^* = \left[\frac{L\gamma^\gamma b^\kappa a^{\gamma+1}}{f_E(1+\gamma)^{1+\gamma}} g^{-\kappa} G_1(g) \right]^{\frac{1}{\kappa-\gamma-1}} \tag{51}$$

$$\xi_H = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}} g^{-\kappa} G_1(g) c^{\kappa-\gamma-1} \right]^{-\frac{1}{\kappa-\gamma-1}} \tag{52}$$

The utility becomes:

$$U_H = \lim_{\eta \to 0} \left\{ \left(\frac{az^*}{c} \right)^{\frac{\eta}{1+\eta}} \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} \right] + \frac{\left(\frac{az^*}{c}\right)^{\frac{\eta}{1+\eta}} - 1}{\eta} \right\} =$$

$$= \left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} \right] + \ln\left(\frac{az^*}{c} \right) =$$

$$= \frac{\ln\left[\frac{L\gamma^\gamma b^\kappa a^{\gamma+1}}{f_E(1+\gamma)^{1+\gamma}} \right]}{\kappa-\gamma-1} + \ln\left(\frac{a}{c} \right) + (1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} - \frac{\kappa \ln g}{\kappa-\gamma-1} + \frac{\ln G_1(g)}{\kappa-\gamma-1} \tag{53}$$

Figure 9 shows the hump-shaped relationship between the utility of the consumers and the restrictiveness of the standard g. Figure 10 presents the negative relationship between the mass of active firms N and the standard g. Figure 11 presents the negative relationship between the market determined quality cutoff z^* and the standard g, under DA and homothetic preferences, since under IA, the cutoff is a constant. Finally, figure 12 presents the relationship between the aggregator ξ and the standard g, under IA and homothetic preferences, since under DA, the aggregator equals one. The standard reduces the aggregator under IA preferences while it increases the aggregator under homothetic preferences.

6.2.4 Planner's Allocation

The planner maximizes the consumer's utility, subject to the resource constraint:

$$\max U = \int_\Omega \left(az\xi q(\omega) - \frac{(\xi q(\omega))^{1+\frac{1}{\gamma}}}{1+\frac{1}{\gamma}} \right) d\omega + \frac{\xi^{-\eta}-1}{\eta}$$

$$\text{s.t. } L = J \int_\Omega Lcq(\omega) - Jf_E$$

The first order conditions with respect to $q(z)$ is given by

$$ax\xi - \xi^{1+\frac{1}{\gamma}}q(z)^{\frac{1}{\gamma}} = \delta Lc$$

where δ is the lagrangian multiplier associated with the resource constraint. The planner's determined cutoff is:

$$z^* = \frac{\delta Lc}{a\xi} \tag{54}$$

Substituting the cutoff into the first order condition yields

$$q(z) = \frac{(az^*)^\gamma}{\xi} \left(\frac{z}{z^*} - 1\right)^\gamma$$

The first order condition with respect to the mass of entrants J is given by:

$$\frac{b^\kappa}{(z^*)^\kappa} \left[\xi \int_{z^*}^\infty k\frac{(z^*)^\kappa}{z^{\kappa+1}} zq(z)dz - \frac{\gamma}{1+\gamma} \int_{z^*}^\infty k\frac{(z^*)^\kappa}{z^{\kappa+1}} (\xi q(z))^{1+\frac{1}{\gamma}} dz - \delta Lc \int_{z^*}^\infty k\frac{(z^*)^\kappa}{z^{\kappa+1}} q(z)dz \right] = \delta f_E$$

$$\frac{b^\kappa (az^*)^{1+\gamma}}{(z^*)^\kappa} \left[G_3(1) - \frac{\gamma}{1+\gamma} G_1(1) - G_4(1) \right] = \frac{f_E \xi(az^*)}{Lc}$$

where $G_4(1)$ is given by:

$$G_4(1) = \int_{z^*}^\infty \kappa \left(\frac{z}{z^*} - 1\right)^\gamma \frac{(z^*)^\kappa}{z^{\kappa+1}} dz = \frac{\kappa F_2(1)}{\kappa - \gamma} \tag{55}$$

Using (38), (26), and (55), we obtain that:

$$G_3(1) - \frac{\gamma}{1+\gamma} G_1(1) - G_4(1) = \frac{G_1(1)}{1+\gamma}$$

Thus, the first order condition with respect to the mass of entrants becomes:

$$\frac{b^\kappa (az^*)^\gamma}{(z^*)^\kappa} \frac{G_1(1)}{1+\gamma} = \frac{f_E \xi}{Lc} \tag{56}$$

Substituting (56) into the resource constraint yields:

$$L = J \left[\frac{Lcb^k}{(z^*)^\kappa} \int_{z^*}^\infty k\frac{(z^*)^\kappa}{z^{\kappa+1}} q(z)dz + f_E \right]$$

$$L = J \left[\frac{Lcb^k (az^*)^\gamma}{\xi(z^*)^\kappa} G_4(g) + f_E \right]$$

$$L = Jf_E \left[\frac{(1+\gamma)G_4(g)}{G_1(1)} + 1 \right]$$

$$J = \frac{L}{f_E} \frac{G_1(1)}{G_2(1)} = \frac{L}{f_E(\kappa - \gamma)} \tag{57}$$

where the result is obtained as:

$$\frac{F_1(1)}{F_2(1)} = \frac{\kappa}{\kappa - \gamma} \tag{58}$$

and

$$\frac{G_1(1)}{G_2(1)} = \frac{\frac{F_1(1)}{F_2(1)(\kappa-\gamma-1)} - \frac{1}{\kappa-\gamma}}{\frac{F_1(1)}{F_2(1)(\kappa-\gamma-1)} + \frac{\gamma}{\kappa-\gamma}} = \frac{1}{\kappa - \gamma}$$

Using (26) and (38) into the definition of ξ (21) we obtain:

$$\xi^{-\eta} = \frac{Jb^\kappa}{(z^*)^\kappa} \left[\xi \int_{z^*}^{\infty} k\frac{(z^*)^\kappa}{z^{\kappa+1}} zq(z)dz - \int_{z^*}^{\infty} k\frac{(z^*)^\kappa}{z^{\kappa+1}}(\xi q(z))^{1+\frac{1}{\gamma}}dz \right] =$$
$$= \frac{Jb^\kappa(az^*)^{1+\gamma}}{(z^*)^\kappa} [G_3(1) - G_1(1)] =$$
$$= \frac{Jb^\kappa(az^*)^{1+\gamma}}{(z^*)^\kappa} G_4(1)$$

Substituting the result into (56) yields the planner's determined cutoff:

$$z^* = \left[\frac{Jb^k c^{\frac{\eta}{1+\eta}} a^{\gamma+\frac{1}{1+\eta}}}{(1+\gamma)^{\frac{\eta}{1+\eta}}} G_4(1)^{\frac{1}{1+\eta}} G_2(1)^{\frac{\eta}{1+\eta}} \right]^{\frac{1}{\kappa-\gamma-\frac{1}{1+\eta}}}$$

Planner's and Market's Allocations

Let us now compare the market allocation with the planner's allocation. To facilitate the comparison, we use subscript m to denote variables in the market allocation, and subscript p in the planner's allocation.

Entry. The planner chooses a mass of entrants identical to the mass of entrants in the market allocation. In fact, letting $J_m(g)$ denote the mass of entrants in the market allocation as a function of the quality standard, and let $J_p = J_m(1)$ denote the planner's entry decision. The ratio of the two measures of entry equals 1 in the absence of a standard, and it is increasing in the restrictiveness of the standard:

$$\frac{J_m(g)}{J_p} = \frac{G_1(g)G_2(1)}{G_2(g)G_1(g)} \qquad g \geq 1 \tag{59}$$
$$\frac{J_m(1)}{J_p} = 1 \qquad g = 1$$

Selection. Let us re-write the market quality cutoff as a function of the standard (30):

$$z_m^*(g) = \left[\frac{J_m(g)c^{\frac{\eta}{1+\eta}}\gamma^\gamma b^\kappa a^{\gamma+\frac{1}{1+\eta}}}{(1+\gamma)^{1+\gamma}} g^{-\kappa}G_2(g) \right]^{\frac{1}{\kappa-\gamma-\frac{1}{1+\eta}}}$$

54

where we used (36). Dividing the planner's cutoff by the market cutoff yields:

$$\frac{z_p^*}{z_m^*(g)} = \left[\left(1 + \frac{1}{\gamma} \right)^\gamma \frac{J_p}{J_m(g)} g^\kappa \frac{((1+\gamma)G_4(1))^{\frac{1}{1+\eta}} G_2(1)^{\frac{\eta}{1+\eta}}}{G_2(g)} \right]^{\frac{1}{\kappa - \gamma - \frac{1}{1+\eta}}} \tag{60}$$

Evaluating the ratio in the market allocation yields:

$$\frac{z_p^*}{z_m^*(1)} = \left(1 + \frac{1}{\gamma} \right)^{\frac{\gamma(1+\eta)}{(1+\eta)(\kappa-\gamma)-1}} \left(1 - \frac{1}{\kappa - \gamma} \right)^{\frac{1}{(1+\eta)(\kappa-\gamma)-1}} \tag{61}$$

where we used (58).

Market Aggregator. Let us now focus on the aggregator ξ. Using the zero profit condition (28) from the market allocation, we obtain:

$$\xi_m(g)(z_m^*(g))^{\kappa-\gamma} = \frac{Lc}{f_E(1+\gamma)} \left(\frac{a\gamma}{1+\gamma} \right)^\gamma \frac{b^\kappa}{g^\kappa} G_1(g) =$$

$$= \frac{c}{f_E(1+\gamma)} \left(\frac{a\gamma}{1+\gamma} \right)^\gamma \frac{b^\kappa}{g^\kappa} G_2(g) J_m(g)$$

Using the first order condition with respect to the mass of entrants (56) from the planner's problem yields:

$$\xi_p(z_p^*)^{\kappa-\gamma} = \frac{cb^\kappa a^\gamma}{f_E(1+\gamma)} J_p G_2(1)$$

Taking the ratio of the two expressions yields:

$$\frac{\xi_p}{\xi_m(g)} = \left(1 + \frac{1}{\gamma} \right)^\gamma \left(\frac{z_m^*(g)}{z_p^*} \right)^{\kappa-\gamma} \frac{J_p}{J_m(g)} \frac{G_2(1)}{G_2(g)} g^\kappa \tag{62}$$

Evaluating it at $g = 1$ yields:

$$\frac{\xi_p}{\xi_m(1)} = \left(1 + \frac{1}{\gamma} \right)^\gamma \left(\frac{z_m^*(1)}{z_p^*} \right)^{\kappa-\gamma} \tag{63}$$

Markups. Let us consider the constant social markup as in [Bertoletti and Etro (2018)](#). To obtain an optimal allocation, in fact, it suffices for all varieties to have the same constant markup m, so that the marginal rate of substitutions equal the marginal rate of transformation. To obtain the markup m let us start from the budget constraint. As $p(z) = mc$, it follows that:

$$J \int_{z_p^*}^\infty p(z)q(z) = mJ \int_{z_p^*}^\infty cq(z)$$

Substituting the result into the budget constraint yields:

$$m = \frac{\kappa - \gamma}{\kappa - \gamma - 1} \tag{64}$$

Comparison Across Preferences

We compare the market allocation under a standard with the planner's allocation, under IA preferences (figure 13), DA preferences (figure 14), and homothetic preferences with too little selection in the market (figure 15) and too much selection (figure 16). Across preferences, we focus on the ratios $\frac{\xi_p}{\xi_m(g)}$ and $\frac{z_p^*}{z_m^*(g)}$ as a function of g. Furthermore, we compare markups and quantitites under the market allocation, the market allocation under the optimal standard, and the planner's allocation. To derive markups and quantities in the market allocation, we normalize the planner's cutoff, entry, and aggregator to one, and derive the corresponding market variables using (63), (61), and (59).

6.2.5 Fixed Cost

This section briefly outlines the case in which the government imposes a quality standard in the market $\bar{z}$, through a fixed cost of production f. The fixed cost f may rationalize the compliance costs that firms must incur due to the standard, or the costs associated with inspections for quality levels. The presence of a fixed cost f leaves the solution to the firms' problem (quantities and prices) and, thus, the revenues, unchanged. However, the profits of a firm with quality z become:

$$\pi(z) = \frac{Lc}{1+\gamma} \left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{(z^*)^\gamma}{\xi} \left(\frac{z}{z^*} - 1\right)^{1+\gamma} - f$$

There exists a firm with quality $\bar{z}$, such that $\pi(\bar{z}) = 0$. The mapping between the fixed cost f and the cutoff-firm $\bar{z}$, equivalent to the quality standard imposed in the baseline model,

is:

$$\frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma}\frac{(z^*)^{\gamma}}{\xi}\left(\frac{\bar{z}}{z^*}-1\right)^{1+\gamma} = f$$

$$\frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma}\frac{(z^*)^{\gamma}}{\xi}(g-1)^{1+\gamma} = f \tag{65}$$

Using (65), average profits become:

$$\bar{\pi} = \frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma}\frac{(z^*)^{\gamma}}{\xi}G_1(g) - f$$

$$= \frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma}\frac{(z^*)^{\gamma}}{\xi}(G_1(g) - (g-1)^{1+\gamma})$$

The zero expected profit condition is then

$$\frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^{\gamma}\frac{b^{\kappa}}{(z^*)^{\kappa-\gamma}g^{\kappa}\xi}(G_1(g) - (g-1)^{1+\gamma}) = f_E$$

Relative to the baseline model, the fixed cost affects both z^* and ξ. Using the market quality cutoff condition $z^* = \frac{c}{a}\xi^{-(1+\eta)}$ into the zero expected profit condition yields the solutions for z^* and ξ. The fixed cost affect the utility of the representative consumer (42) only through ξ. Following the same steps of the baseline model, the utility of the representative consumers becomes:

$$U = \left[\frac{Lb^{\kappa}a^{\kappa}c^{\kappa-\gamma-1}\gamma^{\gamma}}{f_E(1+\gamma)^{1+\gamma}}g^{-\kappa}(G_1(g) - (g-1)^{1+\gamma})\right]^{\frac{\eta}{(1+\eta)(\kappa-\gamma)-1}}\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta}\right] - \frac{1}{\eta}$$

and deriving the closed form expressions for the IA, DA, and homothetic case follows from the baseline model. In particular,

$$U_{DA} = \left[\frac{Lb^{\kappa}a^{\kappa}c^{\kappa-\gamma-1}\gamma^{\gamma}}{f_E(1+\gamma)^{1+\gamma}}g^{-\kappa}(G_1(g) - (g-1)^{1+\gamma})\right]^{\frac{1}{\kappa-\gamma}}\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)}\right]$$

$$U_{IA} = \left[\frac{Lb^{\kappa}a^{\kappa}c^{\kappa-\gamma-1}\gamma^{\gamma}}{f_E(1+\gamma)^{1+\gamma}}g^{-\kappa}(G_1(g) - (g-1)^{1+\gamma})\right]\left[(1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} - 1\right] + 1$$

$$U_H = \frac{\ln\left[\frac{L\gamma^{\gamma}b^{\kappa}a^{\gamma+1}}{f_E(1+\gamma)^{1+\gamma}}\right]}{\kappa-\gamma-1} + \ln\left(\frac{a}{c}\right) + (1+\gamma)\frac{G_3(g)}{G_2(g)} - \frac{\gamma^2}{1+\gamma}\frac{G_1(g)}{G_2(g)} - \frac{\kappa\ln g}{\kappa-\gamma-1} + \frac{\ln(G_1(g) - (g-1)^{1+\gamma})}{\kappa-\gamma-1}$$

While the standard in the baseline model directly affect the selection of firms, the fixed cost also reallocates resources from production to the activities required to comply to the regulation. As a result, the welfare benefits of the standard examined in the baseline case are diminished by the fixed cost. In fact, the optimal standard is smaller in this extension that it is in the baseline case: the fixed cost acts as a downward shift in the optimal g across preferences. As shown in figure 17, for the DA and homothetic case the optimal policy is no standard under certain parameters.

Figure 17: Optimal g Across Preferences - Standard as Fixed Cost

(a) As a function of γ **(b)** As a function of κ
6.2.6 Productivity Heterogeneity and Quality

The baseline model features the simplifying assumption that firms differ exogenously in terms of quality. However, most papers in the literature model firms that differ in terms of productivity and that product quality is a function of firm's productivity (Manova and Zhang, 2017; Feenstra and Weinstein, 2016). This section shows that the results of our baseline model also arise in a model in which quality is a function of firm's productivity.

Consider an extension to the baseline model in which firms differ in terms of productivity ϕ. As it is common in the literature, we assume that ϕ follows a Pareto distribution with CDF: $1 - \left(\frac{\tilde{b}}{\phi}\right)^{\tilde{\kappa}}$. Similarly to the framework of Manova and Zhang (2017), firm's quality is proportional to firm's productivity: $z = \phi^{\frac{1}{\theta}}$, with $\theta > 0$. Moreover, we let the marginal cost of the firm ϕ be proportional to the quality. In particular, marginal costs are equal to cz^{β}. We assume that the elasticity of marginal costs with respect to quality is less than one: $\beta < 1$. This assumption is made for average revenues to be well defined.[61] To obtain a closed form expression for the utility, we restrict the analysis to the linear GTP case, namely $\gamma = 1$.

Firm's profits become

$$\pi(z) = L\xi^{1+\eta} \left[azq(z) - \xi(q(z))^2\right] - Lcz^{\beta}q(\omega)$$

Profit maximization yields the following optimal quantity:

$$q(z) = \left(\frac{a}{2}\right)\frac{z^*}{\xi}\left(\frac{z}{z^*} - \left(\frac{z}{z^*}\right)^{\beta}\right)$$

---

[61]Modeling an endogenous quality choice as (Gaigne and Larue, 2016), in which firms must also pay a fixed cost is highly untractable under GTP preferences. We verified that such a technological assumption does not generate additional distortions in a model with standard CES preferences.

where the market determined quality cutoff equals:

$$z^* = \left(\frac{c}{a\xi^{1+\eta}} \right)^{\frac{1}{1-\beta}}$$

Using the quality cutoff, we can rewrite the performance variables of the firm as follows:

$$p(z) = \frac{c(z^*)^\beta}{2} \left(\frac{z}{z^*} + \left(\frac{z}{z^*} \right)^\beta \right)$$

$$r(z) = \frac{Lca}{4} \frac{(z^*)^{\beta+1}}{\xi} \left(\left(\frac{z}{z^*} \right)^2 - \left(\frac{z}{z^*} \right)^{2\beta} \right)$$

$$\pi(z) = \frac{Lca}{4} \frac{(z^*)^{\beta+1}}{\xi} \left(\frac{z}{z^*} - \left(\frac{z}{z^*} \right)^\beta \right)^2$$

Let us derive the probability distribution for quality. In particular,

$$Pr(\tilde{z} \le z) = Pr(\phi^{\frac{1}{\theta}} \le z) = 1 - \left(\frac{\tilde{b}}{z^\theta} \right)^{\tilde{\kappa}}$$

Thus, we can change the notation and derive the same distribution for quality we used in the baseline model. In fact, quality z follows a Pareto distribution with shape parameter $\kappa = \tilde{\kappa}\theta$ and shift parameter $b = \tilde{b}^{\frac{1}{\theta}}$.

Following the same procedure as the baseline model, the utility of the representative consumer becomes:

$$U = \left[\frac{Lb^\kappa a^{\kappa-2\beta}}{4f_E c^{\kappa-2}} g^{-\kappa} G_1(g) \right]^{\frac{\eta(1-\beta)}{(1+\eta)(\kappa-1)-1-\beta\eta}} \left[2\frac{G_3(g)}{G_2(g)} - \frac{1}{2}\frac{G_1(g)}{G_2(g)} + \frac{1}{\eta} \right] - \frac{1}{\eta}$$

where

$$G_1(g) = \frac{\kappa g^2}{\kappa - 2} - \frac{2\kappa g^{\beta+1}}{\kappa - \beta - 1} + \frac{\kappa g^{2\beta}}{\kappa - 2\beta}$$

$$G_2(g) = \frac{\kappa g^2}{\kappa - 2} - \frac{\kappa g^{2\beta}}{\kappa - 2\beta}$$

$$G_3(g) = \frac{\kappa g^2}{\kappa - 2} - \frac{\kappa g^{\beta+1}}{\kappa - \beta - 1}$$

Figure 18 shows the relationship between welfare and the restrictiveness of the standard for different values of β, under IA preferences. For $\beta = 0$, this extension becomes identical to the baseline model. This implies that our baseline model with firms heterogeneous in quality is equivalent to a model in which firms differ in terms of productivity, and their productivity is proportional to their product quality. The result is independent of the level of θ, as long as the two models match the same distribution of sales.

For $\beta \ne 0$, the marginal costs of production depends on quality. If $\beta < 0$, firm's with high quality also have lower production costs. This scenario assumes that more productive

firms have higher quality and attain cost efficiency. When $\beta < 0$, the sales difference between low-quality firms and high-quality firms increases relative to the baseline model, since high-quality firms are also low-cost firms. In this case, the business stealing bias is reduced relative to the baseline model. Hence, the optimal level of g is smaller.

On the other hand, $\beta > 0$ yields the more realistic scenario in which high-quality firms have higher costs of production than low-quality firms (Manova and Zhang, 2017). In this scenario, the business stealing bias is larger than the baseline case. There are too many low-quality firms operating in the market because 1) their markups are lower and 2) their marginal costs are lower. As a result, when marginal costs and quality are positively correlated the positive welfare effects of the standard are larger. The result also arises under DA and homothetic preferences. Details are available upon request.

Figure 18: Minimum Quality Standard and Welfare ($\eta = -1$)
6.2.7 A Two-Country Framework

Consider a world made of two identical economies, where exporting requires an iceberg trade cost τ. Consumers have GTP preferences. As the two countries are identical, we can normalize per capita income and wages to one in both countries. We assume that the two countries decide a common minimum quality requirement $\bar{z}$, which holds in each nation, and we study how different levels of the iceberg trade cost τ affect the optimal level of the standard.

Let subscript D denote variables related to the domestic economy (domestic sales, profits and so on), and X variables related to exports. Adapting the market-determined quality cut-off to this section's assumptions yields the following market-determined cutoffs for domestic

63

sales z_D^* and for exports z_X^*:

$$z_D^* = \frac{c}{a}\xi^{1+\eta} \tag{66}$$

$$z_X^* = \frac{\tau c}{a}\xi^{1+\eta} \tag{67}$$

When the international authority chooses $\bar{z}$ there are two potential outcomes. First, if $\bar{z} \in [z_D^*, z_X^*]$, only domestic sales are affected: the low-quality firms that sell domestically are forced out of the market but the selection of exporters only depends on the iceberg trade cost τ. Second, if $\bar{z} \in [z_X^*, \infty)$, both domestic sellers and exporters are constrained by the policy. In particular, the minimum quality requirement is so demanding that only high-quality firms that exports are able to remain active. As a result, in this scenario — which appears unrealistic — all firms that are active also export. In this section, we focus on the first case, in which $\bar{z} \in [z_D^*, z_X^*]$. Details on the second case are available upon request.

Firm z profits and revenues in each market $i = D, X$ are identical to baseline model, with the exception that the cutoff z_i^* is destination specific:

$$r_i(z) = \frac{L\tau_i c}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{(z_i^*)^\gamma}{\xi}\left(\frac{z}{z_i^*}-1\right)^\gamma\left(\frac{z}{z_i^*}+\gamma\right)$$

$$\pi_i(z) = \frac{L\tau_i c}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{(z_i^*)^\gamma}{\xi}\left(\frac{z}{z_i^*}-1\right)^{1+\gamma}$$

where $\tau_D = 1$ and $\tau_X = \tau$. Let $g = \frac{\bar{z}}{z_D^*}$. Average revenues in the domestic and foreign economy are given by:

$$\bar{r}_D = \int_{\bar{z}}^\infty r_D(z)\kappa\frac{\bar{z}^\kappa}{z^{\kappa+1}}dz = \frac{Lc}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{(z_D^*)^\gamma}{\xi}G_2(g)$$

$$\bar{r}_X = \int_{z_X^*}^\infty r_X(z)\kappa\frac{(z^*)_X^\kappa}{z^{\kappa+1}}dz = \frac{L\tau c}{1+\gamma}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{(z_X^*)^\gamma}{\xi}G_2(1)$$

The mass of active domestic firms is $J\left(\frac{b^\kappa}{\bar{z}^\kappa}\right)$ while the mass of exporters is $J\left(\frac{b^\kappa}{z_X^{*\kappa}}\right)$. By (66) and (67), $z_X^* = \tau z_D^*$. Therefore, aggregate revenues R are given by:

$$R = J\left(\frac{b^\kappa}{\bar{z}^\kappa}\right)\bar{r}_D + J\left(\frac{b^\kappa}{(z^*)_X^\kappa}\right)\bar{r}_X = \frac{Jb^\kappa Lc}{(1+\gamma)\xi}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma\left[\frac{G_2(g)(z_D^*)^\gamma}{\bar{z}^\kappa}+\frac{\tau G_2(1)}{(z_X^*)^{\kappa-\gamma}}\right]$$

$$= \frac{Jb^\kappa Lc}{(1+\gamma)\xi}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma\left[\frac{G_2(g)(z_D^*)^\gamma}{\bar{z}^\kappa}+\frac{\tau G_2(1)}{(z_X^*)^{\kappa-\gamma}}\right] =$$

$$= \frac{Jb^\kappa Lc}{(1+\gamma)\xi(z_D^*)^{\kappa-\gamma}}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma\left[\frac{G_2(g)}{g^\kappa}+\frac{G_2(1)}{\tau^{\kappa-\gamma-1}}\right]$$

Our market clearing condition ($R = L$) becomes:

$$\frac{Jb^\kappa c}{(1+\gamma)\xi(z_D^*)^{\kappa-\gamma}}\left(\frac{a\gamma}{1+\gamma}\right)^\gamma\left[g^{-\kappa}G_2(g)+\tau^{-(\kappa-\gamma-1)}G_2(1)\right] = 1 \tag{68}$$

Expected profits are computed as:

$$E[\pi] = \left(\frac{b^\kappa}{\bar{z}^\kappa}\right) \int_{\bar{z}}^\infty \pi_D(z)\kappa \frac{\bar{z}^\kappa}{z^{\kappa+1}} dz + \left(\frac{b^\kappa}{(z^*)_X^\kappa}\right) \int_{z_X^*}^\infty \pi_X(z)\kappa \frac{(z^*)_X^\kappa}{z^{\kappa+1}} dz$$

The zero expected profit condition ($E[\pi] = f_E$) becomes:

$$\frac{Lb^\kappa c}{(1+\gamma)\xi(z_D^*)^{\kappa-\gamma}} \left(\frac{a\gamma}{1+\gamma}\right)^\gamma \left[g^{-\kappa}G_1(g) + \tau^{-(\kappa-\gamma-1)}G_1(1)\right] = f_E \tag{69}$$

Let $G_5(g,\tau) = g^{-\kappa}G_1(g) + \tau^{-(\kappa-\gamma-1)}G_1(1)$. Using (66), the aggregator is:

$$\xi = \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}} G_5(g,\tau)\right]^{-\frac{1}{(1+\eta)(\kappa-\gamma)-1}} \tag{70}$$

Using the market clearing condition (68), the first component of the utility function is:

$$\int a\xi z q(z) dz = \int_{\bar{z}}^\infty a\xi z q_D(z) dz + \int_{z_X^*}^\infty a\xi z q_X(z) dz =$$

$$= a\left(\frac{a\gamma}{1+\gamma}\right)^\gamma \frac{Jb^\kappa}{(z_D^*)^{\kappa-\gamma-1}}(g^{-\kappa}G_3(g) + \tau^{-(\kappa-\gamma-1)}G_3(1)) =$$

$$= \frac{a\xi z_D^*}{c}(1+\gamma)\frac{g^{-\kappa}G_3(g) + \tau^{-(\kappa-\gamma-1)}G_3(1)}{g^{-\kappa}G_2(g) + \tau^{-(\kappa-\gamma-1)}G_2(1)}$$

Similarly, the second component becomes:

$$\int_{\bar{z}}^\infty (\xi q(z))^{1+\frac{1}{\gamma}} = \frac{a\xi z_D^*}{c}\gamma\frac{g^{-\kappa}G_1(g) + \tau^{-(\kappa-\gamma-1)}G_1(1)}{g^{-\kappa}G_2(g) + \tau^{-(\kappa-\gamma-1)}G_2(1)}$$

Let $G_6(g,\tau)$ be equal to:

$$G_6(g,\tau) = (1+\gamma)\frac{g^{-\kappa}G_3(g) + \tau^{-(\kappa-\gamma-1)}G_3(1)}{g^{-\kappa}G_2(g) + \tau^{-(\kappa-\gamma-1)}G_2(1)} - \frac{\gamma^2}{1+\gamma}\frac{g^{-\kappa}G_1(g) + \tau^{-(\kappa-\gamma-1)}G_1(1)}{g^{-\kappa}G_2(g) + \tau^{-(\kappa-\gamma-1)}G_2(1)}$$

Using the previous results, and the definition of the cutoff (66), the utility equals to:

$$U = \frac{a\xi z_D^*}{c}G_6(g,\tau) + \frac{\xi^{-\eta} - 1}{\eta} =$$

$$= \xi^{-\eta}\left[G_6(g,\tau) + \frac{1}{\eta}\right] - \frac{1}{\eta} =$$

$$= \left[\frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}} G_5(g,\tau)\right]^{\frac{\eta}{(1+\eta)(\kappa-\gamma)-1}}\left[G_6(g,\tau) + \frac{1}{\eta}\right] - \frac{1}{\eta}$$

Let $\tilde{\xi} = \frac{Lb^\kappa a^\kappa \gamma^\gamma}{f_E(1+\gamma)^{1+\gamma}c^{\kappa-\gamma-1}}$. The utility under the three preferences (IA, DA, and homothetic)

65

is given by:

$$U_{IA} = \tilde{\xi} G_5(g,\tau) \left[G_6(g,\tau) - 1 \right] + 1$$
$$U_{DA} = (\tilde{\xi} G_5(g,\tau))^{\frac{1}{\kappa-\gamma}} G_6(g,\tau)$$
$$U_H = \frac{\ln \tilde{\xi}}{\kappa - \gamma - 1} + G_6(g,\tau) + \frac{\ln G_5(g,\tau)}{\kappa - \gamma - 1}$$

Under the three preferences, we compare the optimal g as a function of τ, restricting the values of τ such that $g^{opt} \in [1, \tau]$.

6.3 Estimation

As a robustness check, we have applied a similar SMM procedure with specific moments from the sales distribution that are pinned down by our parameters of interest. We construct 4 moments: i) the sales advantage of "high-quality" relative to "low-quality" firms[62]; ii) the skewness of the distribution which captures the fact that a standard reallocates sales away from the smallest firms; and iii) two differences: $\log(\tilde{r})_{99} - \log(\tilde{r})_{90}$ and $\log(\tilde{r})_{90} - \log(\tilde{r})_{10}$.[63] We plot the simulates sales distribution given the alternative calibration in Figure 19, which is analogous to the Figure in the main text, and report the estimated parameters. We do not find large discrepancies with our benchmark strategy: $\hat{g}$ is almost identical and has the same time series patterns, as do the other two parameters. The fit with the data distribution is clearly not as close in the alternative calibration.

---

[62]This moment is related to that used to identify the elasticity of substitution in Bernard et al. (2003). Instead of comparing exporters and non-exporters, we compare firms above and below the median in sales.

[63]We point out that moments from other distributions, such as markups and value added, are not used because the data does not allow us to differentiate between exported and domestic components.
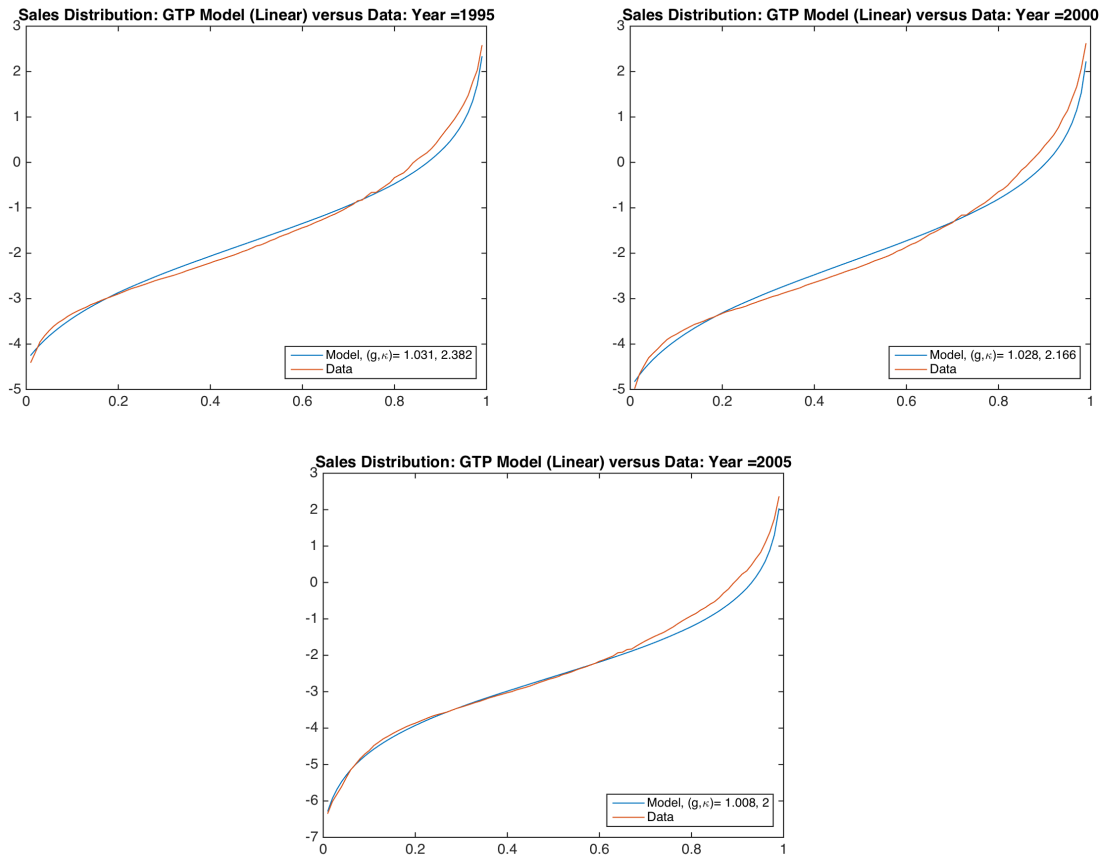

Figure 19: Log Domestic Sales Distribution: Model (Alternative Calibration) VS Data
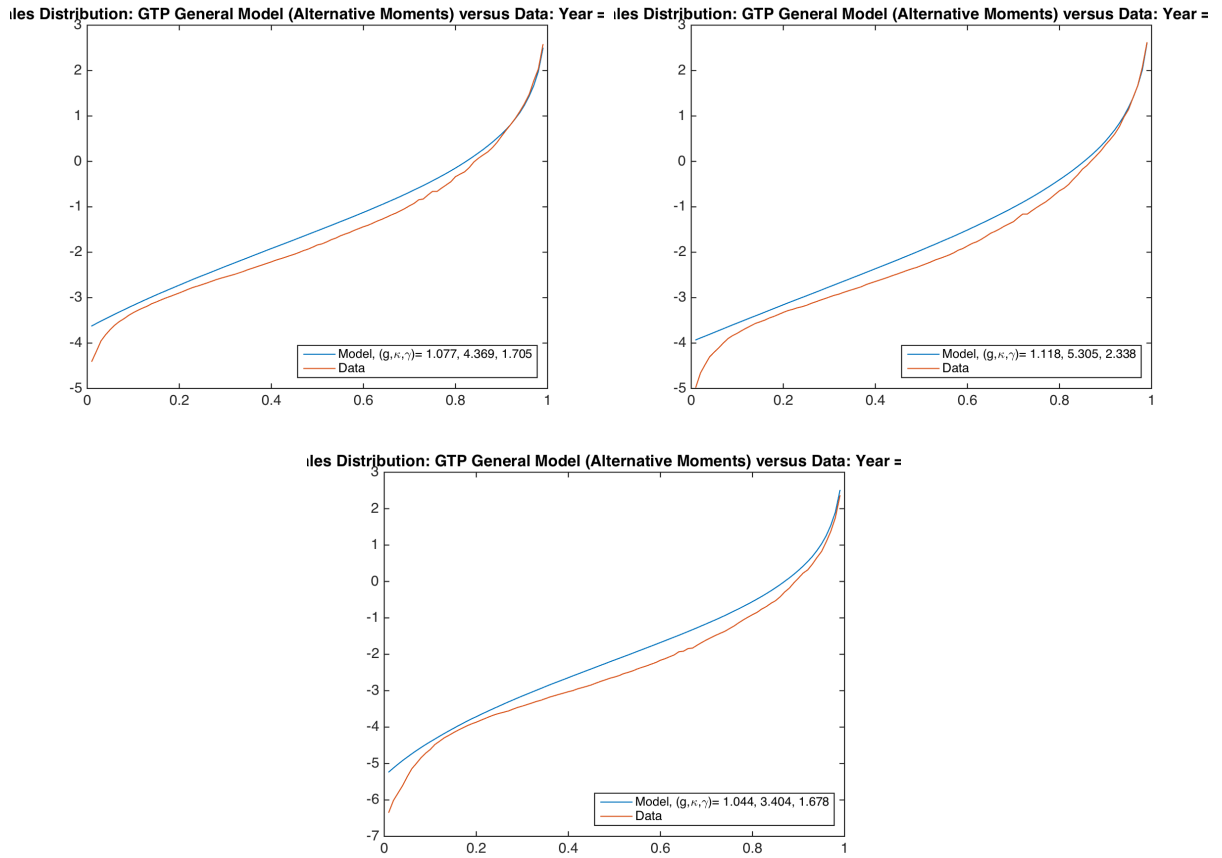

Each Figure plots the CDF of the log sales distribution in the data (red) versus the simulated distribution given the estimated parameters. The parameters of the model are estimated using *only the 4 moments described in the "alternative calibration"*. The model is estimated using the universe of manufacturing firms in each year. The 95% confidence intervals for the parameters in each of the three years are: $\hat{g} = (1.05, 1.11), (1.08, 1.14), (1.03, 1.06)$; $\hat{\kappa} = (0.94, 8.23), (1.26, 8), (2.08, 4.6)$; $\hat{\gamma} = (1.11, 2.50), (1.42, 2.87), (1.27, 2.06)$.

We have also conducted a robustness analysis of the main specification, but with a fixed linear demand: $\gamma = 1$. This restricts the substitution parameter to be smaller than our estimates, which allows firms more market power. In doing so, the largest firms have lower sales as they use the market power to reduce quantity. Figure 20 plots the simulated sales distribution given the estimated $(\hat{g}, \hat{\kappa})$ versus the data. The results are such that the sales of the largest firms are clearly under-estimated.
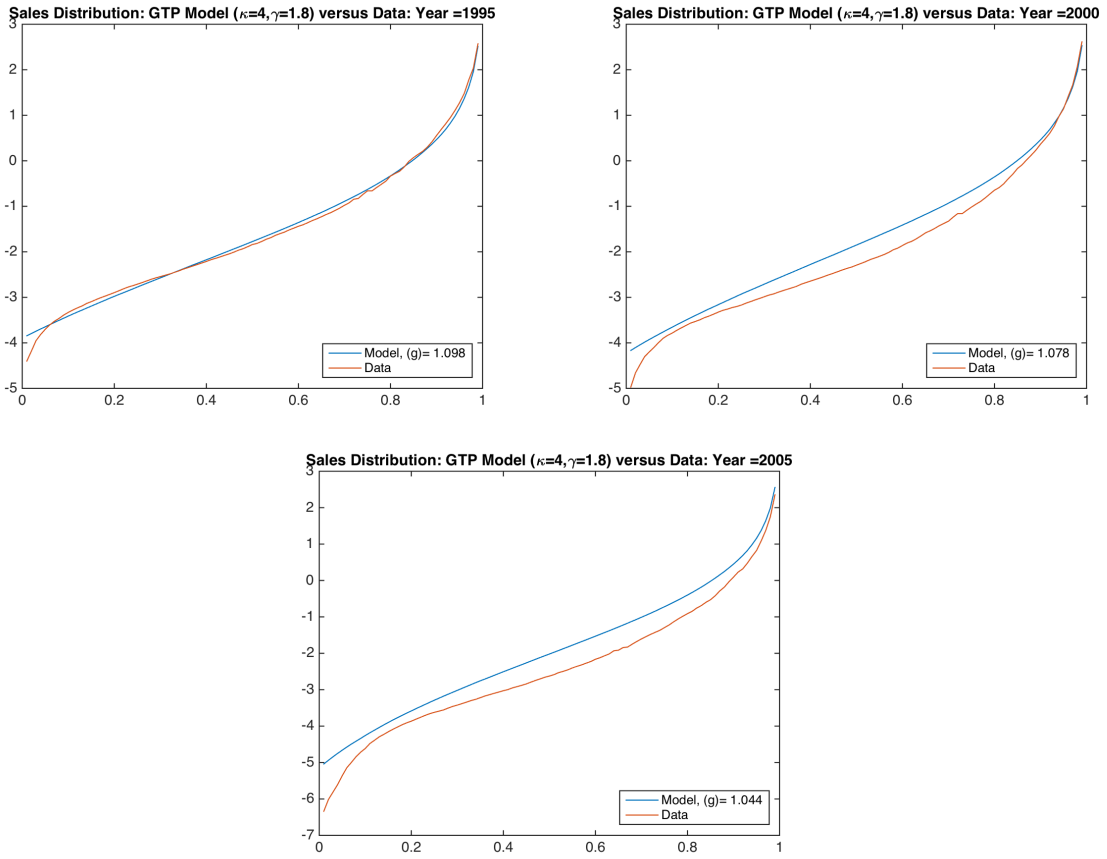

Figure 20: Log Domestic Sales Distribution: Model ($\gamma = 1$) VS Data

Each Figure plots the CDF of the log sales distribution in the data (red) versus the simulated distribution given the estimated parameters. The parameters of the model are estimated using the main specification, but a fixed $\gamma = 1$. The model is estimated using the universe of manufacturing firms in each year. The 95% confidence intervals for the parameters in each of the three years are: $\hat{g} = (1.02, 1.04), (1.02, 1.03), (1.00, 1.02)$; $\hat{\kappa} = (0.94, 2.51), (1.26, 2.29), (2, 2)$.

Finally, we shut down both κ and γ, with the assumption that these are deep parameters and are constant across time. We set $\kappa = 4$ and $\gamma = 1.8$, consistent with the average parameters estimated in the full estimation. Figure 21 plots the simulated sales distribution given the estimated $(\hat{g})$ versus the data.

Figure 21: Log Domestic Sales Distribution: Model ($\gamma = 1.8, \kappa = 4$) VS Data

Each Figure plots the CDF of the log sales distribution in the data (red) versus the simulated distribution given the estimated parameters. The parameters of the model are estimated using the main specification, but a fixed $\gamma = 1.8$ and $\kappa = 4$. The model is estimated using the universe of manufacturing firms in each year. The 95% confidence intervals for the parameters in each of the three years are: $\hat{g} = (1.09, 1.1), (1.07, 1.08), (1.04, 1.05)$.

Table 7: Reduction in Probability of Survival Due to Restrictions by Industry-Year

ISIC	Industry name	1995	2000	2005
1511	Meat	0.4	0.45	0.47
1512	Fish	0.16	0.38	0.2
1513	Fruit & Vegetables	0.35	0.33	0.13

3699	Other Manuf.	0.16	0.84	0.6
	Average	0.42	0.45	0.36

This table reports the reduced probability of producing in each industry given the estimated restrictiveness of the industry. The probability is calculated as $(1 - \hat{g}^{-\tilde{\kappa}})$. It is based on the simulated method of moments estimation for year industry by year.
